Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not constitute or imply its endorsement or recommendation by Jones & Bartlett Learning, LLC and such reference shall not be used for advertising or product endorsement purposes. All trademarks displayed are the trademarks of the parties noted herein. *Varney's Midwifery, Sixth Edition* is an independent publication and has not been authorized, sponsored, or otherwise approved by the owners of the trademarks or service marks referenced in this product.

There may be images in this book that feature models; these models do not necessarily endorse, represent, or participate in the activities represented in the images. Any screenshots in this product are for educational and instructive purposes only. Any individuals and scenarios featured in the case studies throughout this product may be real or fictitious, but are used for instructional purposes only.

The authors, editor, and publisher have made every effort to provide accurate information. However, they are not responsible for errors, omissions, or for any outcomes related to the use of the contents of this book and take no responsibility for the use of the products and procedures described. Treatments and side effects described in this book may not be applicable to all people; likewise, some people may require a dose or experience a side effect that is not described herein. Drugs and medical devices are discussed that may have limited availability controlled by the Food and Drug Administration (FDA) for use only in a research study or clinical trial. Research, clinical practice, and government regulations often change the accepted standard in this field. When consideration is being given to use of any drug in the clinical setting, the health care provider or reader is responsible for determining FDA status of the drug, reading the package insert, and reviewing prescribing information for the most up-to-date recommendations on dose, precautions, and contraindications, and determining the appropriate usage for the product. This is especially important in the case of drugs that are new or seldom used.

Brief Contents

Part I Midwifery

Chapter 1 History of Midwifery in the United States

Chapter 2 Professional Midwifery Today

Chapter 3 Midwifery: Clients, Context, and Care

Part II Midwives as Primary Care Providers

Chapter 4 Introduction to the Care of Women

Chapter 5 Health Promotion Across the Lifespan

Chapter 6 Common Conditions in Primary Care

Chapter 7 Nutrition

Chapter 8 Mental Health Conditions

Chapter 9 Pharmacotherapeutics

Part III Gynecology

Chapter 10 Anatomy and Physiology of the Female Reproductive System

Chapter 11 Menstrual Cycle Abnormalities

Chapter 12 Gynecologic Disorders

Chapter 13 Breast Conditions

Chapter 14 Reproductive Tract and Sexually Transmitted Infections

Chapter 15 Family Planning

Chapter 16 Nonhormonal Contraception

Chapter 17 Hormonal Contraception

Chapter 18 Midlife, Menopause, and Beyond

Part IV Antepartum

Chapter 19 Anatomy and Physiology of Pregnancy

Chapter 20 Genetics

Chapter 21 Prenatal Care

Chapter 22 Pregnancy-Related Conditions

Chapter 23 Medical Complications in Pregnancy

Part V Intrapartum

Chapter 24 Anatomy and Physiology During Labor and Birth

Chapter 25 First Stage of Labor

Chapter 26 Fetal Assessment During Labor

Chapter 27 Support for Women During Labor

Chapter 28 Second Stage of Labor and Birth

Chapter 29 Complications During Labor and Birth

Chapter 30 Third Stage of Labor

Chapter 31 Birth in the Home and Birth Center

Part VI Postpartum

Chapter 32 Anatomy and Physiology of Postpartum

Chapter 33 Postpartum Care

Chapter 34 Postpartum Complications

Chapter 35 Breastfeeding and the Mother–Newborn Dyad

Part VII Newborn

Chapter 36 Anatomy and Physiology of the Newborn

Chapter 37 Examination of the Newborn

Chapter 38 Neonatal Care

Index

Contents

Preface

Acknowledgments

Contributors

Part I Midwifery

With Introduction by Holly Powell Kennedy

Chapter 1 History of Midwifery in the United States

Anne Z. Cockerham

Introduction
Evolution of Nurse-Midwifery's Professional Image and Organization
Evolution of Legal Practice Authority for Nurse-Midwives
Evolution of the Midwifery Scope of Practice
Caring for Underserved Populations
Place of Birth
Nurse-Midwife/Physician Collaboration: Opportunities and Challenges
Documenting the Outcomes of Midwifery Care and Midwifery Research
Nurse-Midwifery Education
Conclusion
References

Chapter 2 Professional Midwifery Today

Deanne R. Williams

Introduction
The Profession of Midwifery
Types of Midwives
Core Competencies
Hallmarks of Midwifery
Accreditation
Certification
Licensure and Regulation
Code of Ethics
Midwives in the United States
Scope of Practice
Practice Patterns

Other Roles for the Modern Midwife
Midwifery as a Worldwide Profession
Conclusion
Resources
References
Appendix 2A Worksheet for Engaging in Global Midwifery
Joyce E. Thompson

Chapter 3 Midwifery: Clients, Context, and Care

Jyesha Wren Serbin, Simon Adriane Ellis, Elizabeth Donnelly, and Kim Q. Dau with Betty Jane Watts Carrington, Heather Clarke, Carolyn Curtis, Nicolle L. Gonzales, Patricia O. Loftman, Felina M. Ortiz, M. Susan Stemmler, and Karline Wilson-Mitchell

Introduction
Social Structure: Power, Privilege, and Bias
Social Determinants of Health and Health Disparities
Socioeconomic Status
Racial Disparities
Sexual Orientation and Gender Identity
Gender-Based Violence
Techniques and Tools to Address Health Disparities in Midwifery Practice
Conclusion
Resources
References
Appendix 3A Reproductive Health Statistics
Mary C. Brucker and Tekoa L. King

Part II Midwives as Primary Care Providers

With Introduction by Lisa L. Paine

Chapter 4 Introduction to the Care of Women

Jan M. Kriebs

Midwife Means “With Woman”
Communication
Approaching the Woman
Collecting the Health History
The Physical Examination
In-Office Laboratory Testing
Establishing a Differential Diagnosis: Making an Assessment
Designing a Plan
Conclusion
Resources
References
Appendix 4A Standard Precautions
Jan M. Kriebs
Appendix 4B Collecting a Health History
Jan M. Kriebs
Appendix 4C The Physical Examination
Jan M. Kriebs
Appendix 4D Breast Examination

Jan M. Kriebs
Appendix 4E Pelvic Examination
Jan M. Kriebs
Appendix 4F Collecting Urinary, Vaginal, Cervical, and Rectal Specimens for Testing and Interpretation of Saline and KOH Slides
Jan M. Kriebs

Chapter 5 Health Promotion Across the Lifespan
Kathryn Osborne
Introduction
Health Promotion: Primary Prevention
Evidence-Based Counseling Interventions
Immunizations
Health Maintenance: Secondary Prevention
Reproductive Life Planning and Preconception Care
Conclusion
Resources
References
Appendix 5A Preconception Care Visit
Mary C. Brucker and Mary Ann Faucher

Chapter 6 Common Conditions in Primary Care
Jan M. Kriebs and Barbara K. Hackley
Introduction
Primary Care
Hematologic Conditions
Cardiovascular Conditions
Respiratory Conditions
Gastrointestinal Disorders and Abdominal Pain
Hepatitis
Conditions of the Genitourinary System
Endocrine Conditions
Neurologic Conditions
Musculoskeletal Disorders
Dermatologic Conditions
Substance Use: Screening and Counseling
Conclusion
Resources
References

Chapter 7 Nutrition
Mary K. Barger
Nutrition and Health
Nomenclature for Nutritional Standards
Macronutrients
Fats
Physiologic Response to Food Intake
Micronutrients: Vitamins and Minerals
Fat-Soluble Vitamins

Water-Soluble Vitamins
Minerals
Role of Vitamin and Mineral Supplementation
Dietary Patterns
Weight Management Counseling and Dietary Patterns
Nutrition Across the Lifespan
Nutrition and Selected Conditions
Conclusion
Resources
References

Chapter 8 Mental Health Conditions

Barbara W. Graves

Screening for Mental Conditions
Overview: Psychotherapy and Pharmacotherapy
Mood Disorders
Depression
Anxiety and Stress Disorders
Mental Health Disturbances Related to the Menstrual Cycle
Perinatal Mental Health
Mental Health Disorders During Pregnancy
Postpartum Mood Disorders
Conclusion
Resources
References

Chapter 9 Pharmacotherapeutics

Mary C. Brucker and Tekoa L. King

Introduction
The Lexicon of Pharmacology
Drug Development and Regulation
Principles of Clinical Pharmacology
Pharmacotherapeutics in Primary Care
Use of Drugs During Pregnancy
Pharmaceuticals Commonly Used During Pregnancy
Conclusion
Resources
References

Part III Gynecology

With Introduction by Patricia Aikins Murphy and Frances E. Likis

Chapter 10 Anatomy and Physiology of the Female Reproductive System

Tekoa L. King and Mary C. Brucker

Introduction
The Breast
The External Female Genitalia
The Internal Female Genitalia

The Bony Pelvis
The Obstetric Pelvis
Clinically Important Aspects of the True Pelvis
The Menstrual Cycle: An Introduction
Steroidogenesis
The Hypothalamic–Pituitary–Ovarian Axis
The Ovarian Cycle
The Endometrial Cycle
Female Sexual Response
Conclusion
Resources
References

Chapter 11 Menstrual Cycle Abnormalities

Debora M. Dole and Mary C. Brucker

Introduction
The Normal Menstrual Cycle and Variations
Amenorrhea
Abnormal Uterine Bleeding
Dysmenorrhea
Conclusion
Resources
References
Appendix 11A Endometrial Biopsy
Wendy Grube and William F. McCool

Chapter 12 Gynecologic Disorders

Sharon M. Bond, William F. McCool, and Mary C. Brucker

Introduction
Screening for Malignancies
Cancer of the Uterine Cervix
Gynecologic Evaluation and Pelvic Pain
Adnexal Masses in Reproductive-Age Women
Disorders of Uterine Origin
Uterine Cervical Variations and Disorders
Disorders of the Vulva
Pelvic Floor Dysfunction Disorders
Fertility/Infertility
Alterations in Women's Sexual Function
Cancer of the Uterus, Ovary, Vulva, and Vagina
Congenital Uterine Anomalies
Conclusion
Resources
References
Appendix 12A Fitting a Pessary
Kathryn Osborne

Chapter 13 Breast Conditions

Joyce L. King

Introduction
Breast Development
Evaluation of Breast Symptoms
Benign Breast Disorders
Breast Cancer
Screening for Women at Low or Average Risk for Breast Cancer
Screening for Women at High Risk for Breast Cancer
Breast Conditions During Pregnancy and Lactation
Conclusion
Resources
References

Chapter 14 Reproductive Tract and Sexually Transmitted Infections

Julia C. Phillippi

Introduction
History and Physical Examination for Vaginal Symptoms and Sexually Transmitted Infections
Vaginal Microbiome
Vaginitis
Bacterial Vaginosis
Vulvovaginal Candidiasis
Atrophic Vaginitis
Other Causes of Vaginitis
Sexually Transmitted Infections
General Management Considerations Specific to Sexually Transmitted Infections
Indications for Sexually Transmitted Infection Screening
Communicating Information About Sexually Transmitted Infections
Chlamydia
Gonorrhea
Pelvic Inflammatory Disease
Syphilis
Chancroid
Lymphogranuloma Venereum
Granuloma Inguinale
Human Papillomavirus
Herpes Simplex Virus
Hepatitis
Human Immunodeficiency Virus
Zika Virus
Protozoal and Parasitic Infections
Trichomoniasis
Pubic Lice (Pthiriasis)
Other Infectious Agents Spread by Sexual Contact
Resources

Chapter 15 Family Planning

Mary C. Brucker

Introduction
Common Terms and Definitions
Family Planning Counseling and the Role of the Midwife
Counseling Women Who Have an Unintended Pregnancy
Induced Abortion
Emergency Contraception
Emerging Trends and Future Contraceptive Methods
Conclusion
Resources
References

Chapter 16 Nonhormonal Contraception
Mary C. Brucker
Introduction
The Effectiveness of Nonhormonal Methods in Preventing Pregnancy
Behavioral Methods
Spermicidal Agents
Barrier Methods
The Intrauterine Device
Permanent Contraception: Sterilization
Conclusion
Resources
References
Appendix 16A Fertility Awareness Methods
Mary C. Brucker
Appendix 16B Fitting Diaphragms

Appendix 16C Intrauterine Device Insertion and Removal
Melicia Escobar

Chapter 17 Hormonal Contraception
Mary C. Brucker
Introduction
Evolution of Hormonal Contraceptive Methods
Mechanism of Action of Hormonal Contraceptives
General Considerations for Hormonal Contraceptives
Clinical Evaluation for Women Initiating or Changing a Hormonal Contraceptive Method
Initiation of Hormonal Contraceptives
Changing from One Hormonal Method to Another
Managing Common Side Effects Associated with Hormonal Contraceptive Methods
Short-Acting Reversible Contraceptives
Combined Oral Contraceptives
Progestin-Only Pills
Transdermal Contraception (The Patch)
Intravaginal Contraceptive Ring
Injectable Depot Medroxyprogesterone Acetate Contraceptives
Long-Acting Reversible Contraceptives
Subdermal Implants

Hormonal Intrauterine Devices
Conclusion
Resources
References

Chapter 18 Midlife, Menopause, and Beyond

Julia Lange Kessler

Introduction
Physiology of Midlife, Menopause, and Aging
Menopause
Terms and Definitions for Menopause
Stages of Reproductive Aging
Diagnosing Menopause
Hallmark Symptoms of the Perimenopausal/Menopausal Period
Lifestyle Strategies for Treatment of Perimenopausal or Menopausal Symptoms
Hormone Therapy for Treatment of Menopausal Symptoms
Nonhormonal Prescription Options for Treatment of Menopausal Symptoms
Complementary and Alternative Therapies
Common Conditions Experienced by Women During Midlife and Beyond
Bone Health, Osteopenia, and Osteoporosis
Conclusion
Resources
References

Part IV Antepartum

With Introduction by Joyce E. Roberts

Chapter 19 Anatomy and Physiology of Pregnancy

Tekoa L. King

Introduction
The Reproductive Organs During Pregnancy
The Breast
The Uterus
Cervical Remodeling During Pregnancy
Hormones of Pregnancy
Fertilization and Implantation
The Placenta
Amniotic Fluid
The Umbilical Cord
The Embryo
The Fetus
Maternal Adaptations to Pregnancy
Fetopelvic Relationships
Conclusion
References

Chapter 20 Genetics
Gwen A. Latendresse
Introduction
Foundations in Genetics
Inheritance Patterns of Genetic Mutations
Chromosomal Disorders
Birth Defects, Incidence, and Risk Identification
Family History and Pedigree Evaluation as Risk Assessment Tools
Screening Tests Versus Diagnostic Tests
Factors That Influence Women's Decision Making
Tests for Genetic and Chromosomal Disorders
Carrier Screening
Screening Tests
Diagnostic Tests
Ultrasound
Genetic Disorder Prevention and Risk Reduction
When Genetic Disorders Are Identified
Financial, Ethical, Legal, and Social Issues in Genetics
Future Trends in Genetic Testing
Conclusion
Resources
References
Appendix 20A Steps in Constructing a Three-Generation Pedigree
Gwen A. Latendresse

Chapter 21 Prenatal Care
Maria Openshaw, Cecilia M. Jevitt, and Tekoa L. King
Introduction
Overview of Prenatal Care
Initial Prenatal Visit
Interval Prenatal Visits
Gestational Weight Gain and Nutrition
Psychosocial Risk Screening and Counseling
Health Education During Pregnancy
Conclusion
Resources
References
Appendix 21A Abdominal Examination During Pregnancy
Tekoa L. King and Cecilia M. Jevitt
Appendix 21B Clinical Pelvimetry
Jennifer M. Demma, Karen Trister Grace, and Tekoa L. King

Chapter 22 Pregnancy-Related Conditions
Nancy Jo Reedy, Esther R. Ellsworth Bowers, and Tekoa L. King
Introduction
Overview of Midwifery Management of Women with Pregnancy-Related Conditions
Common Discomforts of Pregnancy
Early Pregnancy Loss
Fetal Conditions

Placental, Amniotic Fluid, and Umbilical Cord Abnormalities
Cervical and Uterine Abnormalities
Preterm Birth
Premature Prelabor Rupture of Membranes
Membrane Sweeping
Dermatoses of Pregnancy
Peripartum Cardiomyopathy
Red Cell Alloimmunization
Population-Specific Special Considerations During Pregnancy
Techniques for Fetal Surveillance
Conclusion
Resources
References
Appendix 22A Auscultated Acceleration Test
Tekoa L. King

Chapter 23 Medical Complications in Pregnancy
Tekoa L. King and Mayri Sagady Leslie
Introduction
Autoimmune Disorders in Pregnancy
Diabetes
Gastrointestinal Conditions
Hematologic Disorders in Pregnancy
Hepatic Disorders
Hypertension During Pregnancy
Infectious Diseases
Neurologic Conditions
Respiratory Conditions
Thyroid Disorders
Urinary Disorders
Conclusion
Resources
References

Part V Intrapartum
With Introduction by Nancy K. Lowe

Chapter 24 Anatomy and Physiology During Labor and Birth
Cindy M. Anderson and Melissa D. Avery
Introduction
Premonitory Signs and Symptoms of Labor
Factors That Influence the Onset of Labor
Endocrinology of Labor: Parturition Cascade
Clinical Stages of Labor
Maternal Fetopelvic Relationships During Labor
Cardinal Movements of Labor
Maternal Systemic Adaptations in Labor
Fetal Response to Labor

Conclusion
Resource
References

Chapter 25 First Stage of Labor

Jeremy L. Neal, Nancy K. Lowe, Sharon L. Ryan, and Linda A. Hunter

Introduction
Normal Physiologic Childbirth
Definitions of Labor
Premonitory Signs and Symptoms of Labor Onset
The Normal First Stage of Labor
Clinical Correlates of Duration of Labor Studies
Midwifery Management During the First Stage of Labor
Components of Midwifery Care for Laboring Women
Continuing Evaluation During Labor
Conclusion
Resources
References
Appendix 25A Evaluation and Diagnosis of Ruptured Membranes
Jeremy L. Neal, Nancy K. Lowe, Sharon L. Ryan, Linda A. Hunter, and Amy Marowitz

Chapter 26 Fetal Assessment During Labor

Tekoa L. King

Introduction
History of Fetal Heart Rate Monitoring
Fetal Physiology
Methods of Fetal Assessment During Labor
Fetal Heart Rate Patterns
Fetal Heart Rate Pattens That Reflect Fetal Acidemia
Relationship Between Fetal Heart Rate Patterns and Newborn Outcomes
Interpretation and Management of Fetal Heart Rate Patterns
Special Populations
Conclusion
Resources
References
Appendix 26A Intermittent Auscultation During Labor
Tekoa L. King
Appendix 26B Fetal Scalp Electrode
Tekoa L. King

Chapter 27 Support for Women During Labor

Elizabeth Nutter

Introduction
Physiology of Pain
Labor Pain
Women's Experience of Labor
General Principles for Assessment of Labor Pain and Provision of Labor Support
Labor Pain Relief Methods Used in the United States

Nonpharmacologic Methods of Mitigating Pain
Pharmacologic Methods of Mitigating Labor Pain
Conclusion
Resources
References
Appendix 27A Injection of Intradermal Sterile Water Papules for Relief of Low Back Pain in Labor
Tekoa L. King

Chapter 28 Second Stage of Labor and Birth

Lisa Kane Low and Kathryn Osborne

Introduction
Definition of Second-Stage Labor
Normal Course of the Second Stage of Labor
Prolonged Duration of Second-Stage Labor
Descent Abnormalities in Second-Stage Labor
Assessment of Maternal and Fetal Well-Being in Second-Stage Labor
Midwifery Management of the Second Stage of Labor
Preparing for the Birth
Management of the Birth
Hydrotherapy and Waterbirth
Immediately Following the Birth
Conclusion
Resources

Preface

What is the purpose of a clinical textbook today? Current research findings, national guidelines, and evidence-based recommendations can be found online and information needed to practice midwifery changes daily, so why read a book?

Midwives, like all healthcare providers, need some core knowledge about anatomy, physiology, the natural course of physiologic events, and signs or symptoms that indicate deviations from normal. Much of this core material is timeless, and it is valuable to have this information gathered together in one text, available for all of us. Providing an overview of this core knowledge in one place is the first purpose of any textbook.

Occasionally, new research and scientific techniques shed light on old knowledge, and then new understandings and clinical applications ensue. For this reason, it is also important to periodically review the basic knowledge and revisit the evidence that supports practice on a regular basis. Updates of the content in this text found in each new edition serve this second purpose as well. Every 5 years or so, the authors who contribute to this text methodically review midwifery practice in light of current scientific findings, and revise this compendium for the profession.

Over time and through subsequent editions, this text documents the growth of the knowledge base that underlies midwifery practice. Thus, the evolution of this text has a third purpose—it provides documentation of how midwifery practice changes over time.

The first edition of this text was written more than 30 years ago. Prior to publication of this text, midwifery students obtained core knowledge from obstetric textbooks, British midwifery books, journal articles, and nursing publications. Midwifery students and midwives in practice still use these sources, yet perhaps the greatest evolution in the last decade has been the rapid expansion of scientific research and explosion of sources of information. Clinicians today are faced with a bewildering number of studies, guidelines, and ever-changing recommendations from different professional organizations. Thus, the fourth purpose of this book is to review the evidence that supports current guidelines and standard therapeutic interventions.

The voices of authors from practices across the nation allow for a robust recognition of practice variations. The advent of evidence-based care enables midwives to provide care so that shared decision making can be a reality. As society has changed, and midwifery has evolved, so has this text evolved. This edition includes a new chapter that presents an overview of the factors that affect an individual's health beyond the biomedical model. Health is profoundly influenced by social and cultural factors, just as it is influenced by genetics and exposure to infectious organisms. The biomedical model is no longer sufficient as a lens for framing determinants of health. The new chapter introduced in this edition, *Midwifery: Clients, Context, and Care*, is dedicated to the recipients of midwifery care and the midwife pioneers who began modeling holistic care long before the value of such care was recognized by the medical community.

These are the reasons why this text is written and rewritten, in an ongoing cycle. Nevertheless, it is equally important that all readers understand that this text is simply a beginning—a starting point for their exploration of the many facets of midwifery. Today, several complementary midwifery texts are available, and those texts can also be used by individuals in their quest to practice safe, quality midwifery care. Midwives must be lifelong learners, and the Internet is an invaluable resource for ensuring that midwives stay up-to-date with the knowledge needed to be a member of this profession. All readers of this text are encouraged to maintain competency in practice by learning how to stay abreast of current evidence via use of online resources. To that end, clinical chapters list suggested websites to facilitate expansion of knowledge and maintain currency.

Varney's Midwifery is one of the primary texts used in midwifery education in the United States. Forecasting the next 3 decades is an impossible task, but this edition and future editions of this text are intended to help midwives on the journey of knowledge acquisition and evolution of midwifery practice.

—Tekoa L. King,
Mary C. Brucker,
Kathryn Osborne, and
Cecilia M. Jevitt

Acknowledgments

A book is a journey. It has a beginning, an end, and many highs and lows throughout the process. Detours occur. A PubMed search for references can be a black hole of wonders to discover. Fortunately for me, midwifery is also a shared journey and writing this text has been a true collaboration in more ways than I can count.

Thank you, Bill, Kya, Tim, Todd, Deepa, Simon, and Odessa, for being the floor beneath my feet and the heart of my ship. Thank you to Mary Brucker, Kathryn Osborne, and Cele Jevitt for sharing every step, with an extra dose of thanks to Mary for our years of writing partnership. You and I have been on this journey before, and I could not wish for a better partner. Thank you to each of the authors who contributed to this edition—for stepping away from your lives to travel with us, often giving a great deal of your time on short notice. Thank you, Francie Likis and Patty Murphy, for our years of editing partnership and for clearing the path ahead of me so I could share the work we three do in this format. Like most journeys, writing this book was a demanding voyage. It was also a year of travel made light by each of our interactions. In the end, it comes back to you, Bill, with all my love.

—Tekoa L. King

To all those who made this possible: the individuals who welcome midwives into their lives; the midwives on whose shoulders we stand; and the students who are the next generation and beyond. Personally, I thank my friends and family who tolerated my absence, physically or mentally, while the book was being written, especially Nancy, Linda, Cathy, Ted, and Julia et al. And of course, thank you to this team, who is the best—especially Tekoa, who makes the process of writing this book a labor of love.

—Mary C. Brucker

Many thanks to the women and families who have entrusted their health care to midwives (without whom this book would not be necessary), to the contributing authors who shared their time and expertise (without whom this book would not be possible), to Tekoa and Mary for the gentle mentorship they provided as I joined this editorial team, and to my family (especially my husband, Pat) for the unending support and encouragement they provide as I expand my role as a midwife.

—Kathryn Osborne

Midwives' work is never their own, but rather an extension of all the midwives ever known. My special thanks and gratitude go to Elizabeth Sharp, Sr. Jeanne Meurer, Terri Gesse, Anne Scupholme, Dorothea Lang, Kitty Ernst, Joyce Thompson, and Helen Varney, the midwives who grew me. My children, Maura, Lorna, and Connor, are recognized here for the unique and different understanding each gave me of pregnancy, birth, and motherhood. And finally, there aren't enough thanks in the world for my husband, Bill Rowe, who kept his own company while I researched and wrote for this edition.

PART I

Midwifery

HOLLY POWELL KENNEDY

There has been no greater time of opportunity for the profession of midwifery than the one we are experiencing right now in the early twenty-first century. However, as the midwifery profession looks ahead, it is essential that we review both our past and our present to inform future goals and pathways. Otherwise, we are likely to repeat past missteps.

Varney's Midwifery is a classic compendium of knowledge about the profession and the practice of midwifery in the United States, within the global context of caring for women and their families. This sixth edition adds to the past versions both in describing the "practice" of midwifery and in unraveling the complex and political environments in which the profession is situated. As I mentioned in my introduction to the fifth edition of *Varney's Midwifery*, the authors of these introductory chapters capture these accomplishments and challenges extraordinarily well, leaving the reader with a sense of awe at the tenacity, resilience, and grit of midwives and the profession of midwifery.

The *History of Midwifery in the United States*, *Professional Midwifery Today*, and *Midwifery: Clients, Context, and Care* chapters provide an overview of what we know about the history of the profession in the United States beginning with the introduction of European immigrants into North America to current times. Midwives in the United States have struggled for centuries to be recognized for their knowledge and contributions to the health care of women. Meeting those challenges head on, midwives have developed increasingly sophisticated guiding documents, policies, and laws that facilitate their practice and increase access to their services for women. An important addition to this edition is the recognition that caring for women is increasingly challenging in an ever-increasing complex world. While women may not be more challenging than they have been in the past, midwives have expanded their lens to embrace the full scope of their complexities.

In the few short years since the fifth edition was published, there have been significant advances, which are well described in this section. Notably, in the United States, the

profession of midwifery has faced some challenges in defining who midwives are, especially in terms of educational preparation. The various U.S. professional organizations gamely took their charge from the International Confederation of Midwives 2011 passage of global standards for education, regulation, and association and adapted them to this country's context. Along the way, they were able to develop a collaborative working group and a consensus document on principles of midwifery legislation and regulation for the United States—a major accomplishment that was inconceivable a few years ago.[1] One of the reasons they were able to do this was their earlier collective efforts to develop an evidence-based statement on normal physiologic birth—something that they could agree on! This evolution demonstrates that collaboration, as is so nicely discussed in the *Professional Midwifery Today* chapter, is built slowly and is founded on trust. We must work collectively within the profession or we will fail in our mission to improve the health of mothers, women, and their families.

Interprofessional collaboration is another challenge that is well described in this section. Over the decades, the profession of midwifery has increasingly garnered the respect and trust of our obstetric colleagues. The American College of Nurse-Midwives (ACNM) and the American College of Obstetricians and Gynecologists (ACOG) have published a significant statement about our joint practice:

> *ACOG and ACNM believe health care is most effective when it occurs in a system that facilitates communication across care settings and among providers . . . Ob-gyns and CNMs/CMs [certified nurse-midwives/certified midwives] are experts in their respective fields of practice and are educated, trained, and licensed, independent providers who may collaborate with each other based on the needs of their patients.*[2]

Considering the looming obstetrician shortage, the acknowledgment of midwives' respective expertise is critical to ensure women continue to have excellent health care.

A truly important addition to this text is the *Midwifery: Clients, Context, and Care* chapter. This chapter establishes the foundational knowledge for understanding health disparities in the United States and the role of midwifery in reversing health disparities. Not only does it provide the evidence on social determinants of health and theoretical perspectives, it provides narratives by midwives of color to help the reader understand the context of these issues in the United States.

The evidence is clear that midwifery care, especially when delivered in a continuity model, can produce exceptional outcomes. A serious challenge for the profession is to consider how we position midwifery to become the standard of care for all women. Even women who develop complications deserve respectful care that incorporates the context of their lives and communities, in collaboration with midwives' medical colleagues. As women are clearly now "finding their voices," we must nurture their strength and allow for the healing of so many who have been hurt in the past. This edition of *Varney's Midwifery* helps us as colleagues who are devoted to that mission. As midwives, we hold the trust of each woman who comes to us for care, and it is our responsibility to assure every woman that our care is stellar. Midwifery is strong and is working day by day with women to strengthen their health and, through them, the

health of the world.

CHAPTER

1

History of Midwifery in the United States

ANNE Z. COCKERHAM

Introduction

History matters. Midwives cannot care for women, newborns/infants, and families without exploring their histories: Which challenges and opportunities have these individuals faced? What are the effects of the social, economic, familial, spiritual, physical, and political situations in which they live? Likewise, members of the midwifery profession must understand the profession's history, the contextual aspects of midwifery practice, and the ways in which those experiences have shaped the profession today.

The history of midwifery is extensive. The work of all midwives, in the many settings and periods over the course of history, is worthy of both exploration and celebration—but that is not possible in a chapter designed to present an overview. In the United States today, an individual who seeks a path to professional midwifery can become either a certified nurse-midwife, a certified midwife, or a certified professional midwife. The *Professional Midwifery Today* chapter describes the differences in midwifery education and scope of practice for the various types of midwives. This chapter focuses primarily on nurse-midwifery, and more recently certified midwifery, as the profession has developed and evolved in the United States. Readers interested in the broader history of all types of midwives in the United States can access a wide-ranging body of literature that documents the accomplishments of—and challenges faced by—non-nurse-midwives.[1-6] More detailed histories can be found in sources such as *A History of Midwifery in the United States: The Midwife Said Fear Not* by Helen Varney and Joyce Thompson[7] and *Midwifery and Childbirth in America* by Judith Rooks.[8]

To help readers explore key concepts and themes that inform the midwifery profession, this chapter is organized thematically, rather than chronologically. It addresses the eight themes that have underscored the profession since its inception and continue to bear upon the profession today:

1. *Public image.* During the birth of the nurse-midwifery profession, midwives built on their strong reputation associated with thousands of years of midwifery, yet also struggled to overcome a negative public image stemming from the "midwife problem"—a label attached to the profession by the medical establishment (i.e., physicians). Since that time, nurse-midwives have worked to craft a positive image and gain self-determination by organizing, communicating with one another and the public, and developing and maintaining publicly visible and understandable standards. The public image that midwives are less qualified than physicians to care for low-risk women continues to be addressed today, albeit to a much lesser extent.
2. *Legal authority.* Obtaining the legal authority to practice has been a challenge since the introduction of nurse-midwifery in the United States. Although the earliest nurse-midwives attained legal practice authority in only a few locations, through the efforts of dedicated members of the profession, that list of locations gradually expanded to include every state within the United States. Autonomous legal authority to practice is an ongoing focus of the work of the certified nurse-midwives and certified midwives today.
3. *Scope of practice.* At the profession's inception, nurse-midwives' scope of practice

encompassed maternity care, including prenatal care. Some early nurse-midwives also provided public health care to meet the needs of the communities they served. As the profession evolved, midwives gradually added family planning, gynecologic care, primary care, and specific "advanced skills." These additional elements became part of midwives' scope of practice, thereby enabling these clinicians to better meet their patients' needs. The midwifery scope of practice will continue to evolve as knowledge and healthcare technologies are applied to clinical practice.

4. *Care of underserved populations.* The earliest nurse-midwives initiated and maintained services to meet the needs of the most underserved populations during that era. Midwives have continued caring for members of these populations since then. Despite the increased frequency and severity of medical and other risk factors in these populations, midwifery care has been associated with exemplary outcomes. Midwifery continues to be strongly associated with care for underserved populations today.
5. *Place of birth.* Nurse-midwives initially attended births only in women's homes. As more women began to give birth in hospitals, however, midwives shifted their practice to serve women in that setting. Midwives brought characteristic midwifery practices such as natural childbirth and family-centered care into the hospital setting. During the 1970s, with increased consumer demand for options outside the hospital, midwives responded by expanding services for women in home birth settings and birth centers.
6. *Relationships with other healthcare providers.* Although midwives and physicians share a vision of providing optimal health care, the two groups have faced challenges in negotiating professional boundaries in collaborative care. Despite their periodic conflicts, midwives and obstetricians have achieved consensus and provide collaborative care in many settings. Today interprofessional collaboration is increasingly recognized and valued.
7. *Research.* From the profession's beginnings, nurse-midwives have demonstrated their dedication to documenting the outcomes of midwifery care to demonstrate its quality, safety, and effectiveness. Midwifery scholars and clinicians have created a rich heritage of research and theory, encompassing a wide variety of topics related to midwifery and women's health. Midwifery's professional organizations and journals have played an important role in the development and support of researchers and in disseminating the new knowledge generated through midwife-led research.
8. *Midwifery education.* All nurse-midwives and certified midwives are connected to one another through a long lineage of educational programs, beginning with two "first-generation" programs. Although midwifery educational programs have taken advantage of opportunities and faced challenges in providing sustained service to the profession and students, midwifery educators have consistently sought to align curricula with foundational principles of midwifery practice and, at the same time, incorporate innovative educational elements such as early adoption of distance learning and simulation.

Evolution of Nurse-Midwifery's Professional Image and Organization

The practice of midwifery and the term "midwife" have ancient roots. In many parts of the United States, apprentice-trained midwives served local communities with distinction, but as a whole, the profession had no legal status or national recognition during the 1800s and early 1900s. In large part, this lack of status developed as part of changing societal trends and the increasing interest in allopathic medicine that emerged during the first decades of the twentieth century. As a result, midwifery was often misunderstood and lacked power and cohesion as a profession.

Thus, in the 1920s, when visionary leaders in nursing, public health, and medicine sought to revitalize midwifery in the form of *nurse*-midwifery, they faced an uphill battle to craft an image that combined the best of the timeless tradition of midwifery with the modern standards and approaches adopted primarily by public health nurses. This rebranding of the ancient art of midwifery into the profession of modern nurse-midwifery required that nurse-midwives organize, communicate with one another and the public, and develop and maintain publicly visible and publicly understood standards for the profession.

Midwifery Prior to the Twentieth Century

Although birth customs among Native American cultures in the Americas are not extensively documented, what is available consistently shows women being supported by several other women and use of upright positions for giving birth. Prior to the 1800s, midwives were the leaders in the care of women during childbirth, which was then a woman- and home-centric social event. Midwives enjoyed the respect of community members, who greatly valued midwives' experience. Many midwives were trained through an apprentice model, and their knowledge grew from the needs of the community members. Some midwives had more formal education, including midwives in various immigrant groups who trained in Europe.

Midwives' image began to change during the 1800s, as male physicians gradually extended their practice into obstetrics.[9] Medical training and formal education, which were available only to middle- and upper-class men, started to include knowledge about obstetrics in response to the growing body of knowledge being developed in Europe. Physicians in the United States began to recognize that being present at a woman's birth would likely result in a long and lucrative doctor–patient relationship. A prominent Harvard physician wrote in 1820:

> *Women seldom forget a practitioner who has conducted them tenderly and safely through parturition. . . . the practice of midwifery becomes desirable to physicians [and] ensures to them the permanency and security of all their other business.*[10(pp79-80)]

Use of hospitals for labor and birth, forceps, obstetric anesthesia, and techniques to conquer puerperal fever were widely adopted at the beginning of the twentieth century. These obstetric practices were not accessible to midwives, whose knowledge gradually became viewed by the

public as outdated.[9] At the time, women were not considered to have the mental capacity for higher learning and were excluded from admission to organizations devoted to higher learning. Historian Judy Litoff writes that by 1800, the United States had four medical schools but women were "systematically excluded from attaining a medical education at the precise time when knowledge of the scientific advances in obstetrics would have enabled them to become more competent midwives."[2(p9)] Historian Laurel Thatcher Ulrich further argues that midwives' decline occurred because "Midwives were 'experienced,' whereas physicians were 'learned.' Because the base of the midwives' experience was shared by all women, their authority was communal as well as personal."[11(p134)]

Furthermore, midwives were generally isolated from one another and lacked national or local organizations, journals, or other means of communicating about the profession. European immigrant communities included well-prepared midwives, but these immigrant midwives often did not speak English or have access to the existing healthcare system.[12] African American midwives in the rural South usually could not gain access to formal education. Other midwives serving their communities faced similar challenges, including white "granny" midwives in Appalachia,[2] midwives in the Ozarks of southern Missouri,[13] "parteras" of Spanish descent in California and the Southwest,[14,15] and sanba midwives from Japan in Hawaii and the Pacific Northwest.[16] In summary, as the nineteenth century drew to a close and the twentieth century began, midwives' influence and activities were becoming increasingly more limited across the United States. Lack of access to formal education and scientific developments, no licensure or organization, lack of a means of communication as a profession, and changes in public perception all combined to prevent midwives in many parts of the United States from having access to the official healthcare system during this era.

The "Midwife Problem" During the Early 20th Century

As traditional midwives' sphere of influence continued to shrink, a large and powerful group of physicians, nurses, social reformers, and public health officials put forth the claim that the United States had a "midwife problem."[17] Supporters of this theory argued that uneducated, unregulated midwives were the main cause of maternal and infant morbidity and mortality rates that far exceeded those of most European countries.[2,18] For example, nurse Carolyn Van Blarcom wrote in the *American Journal of Public Health* in 1914 that "it is due in great measure to the ignorance and neglect on the part of midwives that many babies become blind from . . . ophthalmia neonatorum."[19(p197)] Physician Anna Rude's 1923 article in the *Journal of the American Medical Association*, titled "The Midwife Problem in the United States," described the "inadequacy of our laws governing midwives, which contain neither uniform provisions nor required standards."[17(p1)] Some physicians argued for the total abolition of midwives and for legal prosecution of violators. Others, including prominent public health officials, promoted close regulation of midwifery and control over midwives' education, rather than eliminating midwifery practice.[2] Within the context of this "midwife problem," the medical, nursing, and public health communities moved to consolidate power and authority over midwives and childbearing.

In reality, those who argued that midwives were the sole cause or even the most significant cause of poor obstetric outcomes were incorrect. From 1915 until the mid-1930s, physicians' use of obstetric interventions, surgeries, and medications increased and a remarkable rise in maternal and infant mortality followed. A committee of the New York Academy of Medicine reported in 1933 that the maternal death rate for surgeons' practice was 9.9 per 1000 live births, and that for obstetricians' practice was 5.4 per 1000 live births.[2] By comparison, home birth midwives who received public health instruction had the lowest maternal death rate—1.4 per 1000 live births.[2] The true causes of poor obstetric outcomes in the United States were actually quite complex, and included lack of prenatal care that could have identified treatable problems; low standards of education for all providers of maternity care, including physicians; intervention by physicians with unproven and often dangerous obstetric techniques; and high rates of puerperal infections due to patient-to-patient contamination among the growing number of women giving birth in hospitals.[20]

During the 1920s, a handful of nursing, medicine, and public health leaders proposed a solution to "the midwife problem": the training of public health nurses as midwives. This new profession would need to carefully craft its public image as well-educated professionals; America's first nurse-midwives strived to meet that goal from the 1920s and beyond. In 1925, Mary Breckinridge opened the first nurse-midwifery clinical service in Kentucky, called the Frontier Nursing Service (FNS) (**Figure 1-1**). At FNS, British-trained nurse-midwives introduced professional maternity and public health care to women and families in isolated mountain communities, followed strict medical directives that had been written by a medical advisory group, and maintained high-quality records to document the outcomes of their care. On the East Coast, the Maternity Center Association (MCA), a group of nurse-midwives in New York City, provided and supervised professional maternity care to impoverished women whose communities had suffered from high rates of morbidity and mortality, maintained clearly articulated collaborative relationships with physicians, and carefully documented the results of their care.

Figure 1-1 A nurse-midwife of the Frontier Nursing Service on a home visit in Kentucky, circa 1950. Reproduced with permission from Frontier Nursing Service, Hyden, Kentucky.

1955: A Professional Organization for Nurse-Midwives

Building on the work of the FNS, MCA, and others between the 1920s and the 1950s, nurse-midwives recognized that a crucial element for the success of the profession would be the establishment of a professional organization. Several attempts during this period laid important groundwork, including the Frontier Nursing Service–focused American Association of Nurse-Midwives (AANM) and the nurse-midwifery section within the National Organization of Public Health Nursing (NOPHN). For various reasons, including disagreements about the role of physicians, optimal practice settings for nurse-midwifery, and inclusion criteria for the profession and professional organizations, neither the AANM nor the NOPHN were deemed to be the ideal vehicle for a unifying professional organization for nurse-midwives.[21]

Ultimately, the foundational work would come to fruition with the establishment of the American College of Nurse-Midwives (ACNM). Beginning in 1954, Sister M. Theophane Shoemaker, director of the Catholic Maternity Institute (CMI) in Santa Fe, New Mexico, chaired the Committee on Organization. Within a few months of beginning their work, Committee on Organization members articulated objectives and organizational structures, defined nurse-midwifery, set educational standards for nurse-midwifery schools, designed and mailed a questionnaire to prospective members, wrote and mailed two of the eventual six *Organization Bulletins of the Committee on Organization*, and organized upcoming meetings.[22,23] At a May 1955 meeting, the Committee on Organization voted unanimously to proceed with formation of the American College of Nurse-Midwifery. The incorporation took place on November 7, 1955, in New Mexico; members selected that location because it was

one of the few states in which nurse-midwives were practicing and the incorporation process was relatively straightforward.[24] See **Figure 1-2**.

Figure 1-2 Original signators of the *Articles of Incorporation* of the American College of Nurse-Midwifery. From left to right: Sister Theophane Shoemaker CNM, MMS; Pat Simmons CNM; Ann Fox CNM; Sr. Judith Kroska CNM, MMS.

Reproduced with permission from American College of Nurse-Midwives.

The new professional organization provided a vehicle through which nurse-midwives could communicate with one another and strategize about how to move their professional interests forward. Rita Kroska designed the organization's seal in 1955 (**Figure 1-3**).[25] The large shield is encircled by a ribboned band containing the inscription, "AMERICAN COLLEGE OF NURSE-MIDWIVES, NEW MEXICO, Nov. 7, 1955. *health and wellbeing of family life, particularly the mother and infant.*"[25] Placing a hyphen between the words "nurse" and "midwife" is a critical piece of punctuation, as it makes "nurse-midwife" a unique, singular profession.

Figure 1-3 The seal of the American College of Nurse-Midwives.

Reproduced with permission from American College of Nurse-Midwives.

Just a few days after ACNM was incorporated, the "First Convention" was held in Kansas City with 17 nurse-midwives in attendance, representing 8 states. The next month, December 1955, the ACNM published the first issue of the *Bulletin of the American College of Nurse-Midwifery*, which included a description of the "prevailing spirit" of the organization:

> *Of all that occurred at the first convention, you would have enjoyed most the fine spirit of unity and enthusiasm which was characteristic of the meetings. The opportunities for frank discussions in the informal, friendly meetings did much to supply the encouragement necessary for launching a new organization full of promise. Our Motto: VIVANT! Let them live!*[24(p4)]

In the second issue of the *Bulletin*, ACNM President Hattie Hemschemeyer reinforced the importance of organizing, communicating, and developing and maintaining professional standards. After reporting that the ACNM had already grown to 124 members, Miss Hemschemeyer wrote:

> *Membership carries with it the need for deliberation and thoughtful action on our part. The college must select carefully the work it undertakes and then do well the work it has undertaken. We need to work with dedication and conviction. . . . We have a pioneer job to do, and if we work as well and as constructively in a group as we have in the past as individuals, we can help to improve professional*

competence, provide better service and educational programs, and make fuller use of resources. The future looks bright.[26(pp5-6)]

A Professional Journal: 1950s to the Present

Beginning with the first issue of the *Bulletin of the American College of Nurse-Midwifery* in 1955, the professional midwifery journal has played a pivotal role in developing nurse-midwifery as a profession. As early as January 1957, a *Bulletin* article informed readers of the importance of participating in the publication of salient articles.[27] The article noted the crucial role that the professional organization and its journal would play in advancing nurse-midwifery as well as remaining true to its ideals:

> *Now that we have a forum, we are in a position to express our spontaneous ideas. . . . The contribution of the nurse-midwife cannot be borrowed from other disciplines. Its uniqueness must be spontaneously defined by nurse-midwives. Then we, as a college, can present these ideas with conviction because they are our own. Responsibility for our growth and influence as a professional group rests squarely on our membership and our leadership.*[27(pp1-2)]

Over time, changes in the name of the national midwifery journal reflected the broader changes in the professional organization and midwifery practice. Between 1955 and 1968, the journal was called the *Bulletin of the American College of Nurse-Midwifery*. When ACNM changed its name in 1969 to the American College of Nurse-Midwives, the *Bulletin* became known as the *Bulletin of the American College of Nurse-Midwives* until 1972. From 1973 to 1999, it was published as the *Journal of Nurse-Midwifery*. In 2000, in response to the expansion of midwifery scope of practice, the journal became *Journal of Midwifery & Women's Health* and remains so today.

Education Program Accreditation

When nurse-midwives founded ACNM in 1955, they recognized the need to establish and maintain high standards for nurse-midwifery education. Objective (d) of Article II of the first Articles of Incorporation was "To plan and develop, with the assistance of allied educational groups, educational programs in nurse-midwifery that will meet the qualifications of the profession."[28(p146),29] By 1960, nurse-midwives were in deep conversation about accreditation for midwifery education programs. Citing the recent growth in midwifery programs, Vera Keane argued that ACNM was the "logical group to establish and support" accreditation. Furthermore, Keane emphasized, accreditation is ideally a "cooperative enterprise" between "accreditors with long range vision and high ideals" and educators who are "willing to share their concerns fully and honestly." According to Keane, benefits of the accreditation process include accreditors' ability to objectively view curricula and assist educators in producing the best nurse-midwives.[30(pp39-41)]

The accreditation of nurse-midwifery education programs was well established by the early

1970s. In 1982, the ACNM Division of Accreditation (DOA) was first recognized by the U.S. Department of Education (USDOE) as a national accrediting body, now named Accreditation Commission for Midwifery Education (ACME). This recognition through accreditation continues today for all midwifery education programs, including those that offer master's and doctoral education, and assures that the curricula pursued by these programs meets educational standards.

Certification of Nurse-Midwives

National certification of individual nurse-midwives was another crucial step forward in establishing publicly recognized standards within the profession. Certification assures consumers that the midwife has appropriate credentials for practice. In 1971, ACNM members voted to approve a bylaws change that included requiring national certification for graduates of accredited nurse-midwifery education programs. In her article about the change, Joyce Cameron detailed the historical background of certification, responded to questions about the purposes of certification, and addressed how national certification affected licensure for nurse-midwifery and the process for national certification.[31] In addition, her article described how certification would be handled for nurse-midwives qualified prior to 1971.

In 1994, ACNM responded to requests from state regulatory agencies to take a leadership role in setting the standards for the credentialing of professional midwives who did not have a nursing background. Using the same criteria specified for nurse-midwifery education programs, the ACNM DOA developed criteria for basic midwifery education programs for non-nurse midwives, and the ACNM Certification Council committed itself to the testing and certification of graduates from ACNM DOA-accredited midwifery programs, who would receive the credential of Certified Midwife (CM).[32] These midwives meet the same endpoint academic and clinical objectives as nurse-midwives. The first education program for non-nurse (direct-entry) midwives preaccredited by the ACNM DOA was established in 1996.

In May 2001, the U.S. Department of Education renewed its recognition of the ACNM Division of Accreditation for preaccreditation and accreditation of nurse-midwifery education programs, and also recognized the expansion of the scope of its activities to include preaccreditation and accreditation of direct-entry midwifery education for the non-nurse.[28] In 2008, the name of the DOA changed to the Accreditation Commission for Midwifery Education (ACME).

Summary

Midwives have both benefited from and struggled with the image associated with the word "midwife." After millennia of experience attending most women's births, midwives' image began to suffer in the late nineteenth century, and the early twentieth century witnessed a well-publicized campaign against the "midwife problem." The new, hybrid profession of nurse-midwifery worked against the negative images, and members of the profession have continued this fight through organization, communication, and developing highly visible professional standards.

Evolution of Legal Practice Authority for Nurse-Midwives

The legal authority to practice nurse-midwifery has been one of the most important determinants in the expansion of midwifery practice in the United States. Initially, nurse-midwifery practice was allowed in only a few jurisdictions. Over time, however, the diligent work of many professionals contributed to the expansion of legal practice and to the involvement of midwives in legislative issues.

Gradual Expansion of Legal Practice Authority: 1920s to 1980s

For the first four decades after the inception of nurse-midwifery in the United States, nurse-midwives had clear legal practice authority in only a limited number of locations, including New York City (Maternity Center Association), Kentucky (Frontier Nursing Service), New Mexico (Catholic Maternity Institute), and a few other areas. Although nurse-midwives were in demand as maternity nursing educators, nursing service staff members, supervisors in hospital obstetrics departments, and consultants in federal and international health organizations, nurse-midwives could legally practice clinical nurse-midwifery in only a few areas for the first several decades of the profession's existence.[33]

The tide began to turn during the 1960s. Nurse-midwifery leaders assessed where nurse-midwives were practicing and demonstrated their commitment to educating midwives about legal practice authority issues. The American College of Nurse-Midwifery carried out a survey in 1961 and 1962 to investigate various aspects of midwifery practice, including the number of nurse-midwives actively practicing clinical midwifery. Results of the survey indicated that 66 of the 213 respondents (approximately 31%) were providing direct midwifery services at that time.[34] A number of articles throughout the 1960s informed *Bulletin of the American College of Nurse-Midwifery* readers about national and state-based legal practice issues.[35,36]

During the 1970s and 1980s, nurse-midwives made major progress, both in articulating official commitment to gaining and maintaining legal practice authority and in expanding the number of jurisdictions in which nurse-midwives could practice. In 1974, the ACNM Legislation Committee participated in the Workshop on the Legal Status of Nurse-Midwifery and subsequently prepared the *Position Statement on Nurse-Midwifery Legislation*. The statement lamented the "barrier[s] to the optimal growth and development of nurse-midwifery due to serious ambiguities in the legal base for practice" and recommended "separate statutory recognition . . . as the basis for nurse-midwifery practice. To the extent possible, this legislation should be uniform throughout the United States and its jurisdictions."[37(p24)]

Keeping Nurse-Midwives Informed About Legislative Issues

In 1976, the *Journal of Nurse-Midwifery* published a theme issue that focused on midwifery-related legislation. The report contained positive news as well as cautionary notes. The authors concluded that nurse-midwifery at that time was "On the whole, a fairly open field.

With few exceptions, laws of states and jurisdictions are not restrictive or clearly prohibitive of the development of nurse-midwifery." However, despite "the trend . . . toward passage of enabling legislation in most states, it is also evident that in many of those states nurse-midwives are still not practicing and that in others, only one or two are employed."[38(p19)]

In 1984, the *Journal of Nurse-Midwifery* again devoted an issue to the legislative status of nurse-midwifery practice in each state, the District of Columbia, Puerto Rico, and the Virgin Islands. In the decade that had passed since its first survey of legal practice authority legislation, much had changed, yet challenges persisted. Nancy Cuddihy described both:

> *The good news is that Certified Nurse-Midwives have established a legal basis for practice in all but two jurisdictions in the United States. The bad news is that this legal basis for practice is a patchwork collection of various nursing and medical practice acts, few of which allow for independence or self-regulation of nurse-midwifery as a profession. This legislative jumble is manifested in the fact that there are five different types of jurisdictional agencies that are currently empowered to regulate nurse-midwives. This lack of uniformity of legislation has been and will continue to be a problem for the profession in attempting to translate nurse-midwifery to legislatures, executive agencies, and other institutions that make public policy.*[39(p55)]

By the early 1990s, further legislative and regulatory changes had occurred and the Political and Economic Affairs Committee of the ACNM assembled a legislative update. In 1992, the *Journal of Nurse-Midwifery* published this report in two parts.[40-42] Organized by ACNM region, the report included information about practice-regulating agencies, statutes and regulations, prescriptive authority, continuing education requirements, insurance reimbursement for midwifery services, and regulation of birth centers.[41,42] The 1992 update included positive news about "significant improvement toward autonomy in CNM practice," including some form of prescriptive authority in 36 states (compared with 18 states in 1984) and mandated third-party reimbursement in 27 states (compared with 14 states in 1984).[40(p159)]

Prescriptive authority for nurse-midwives gradually followed. Today, nurse-midwives have been granted authority to write prescriptions in all 50 states and in the District of Columbia. Aspects of that prescriptive authority were profiled in the *Journal of Midwifery and Women's Health* by Kathryn Osborne in 2011 and 2015.[43,44]

Summary

After the introduction of nurse-midwives in the United States in the 1920s, the legal authority to practice nurse-midwifery was available in only a few areas of the country. Following decades of legislative action, nurse-midwives now have the legal authority to practice and prescriptive authority in all parts of the United States.

Evolution of the Midwifery Scope of Practice

Another factor influencing the image of the profession has been midwifery's response, via shifts in scope of practice, to the changing needs of the women and families whom midwives serve. Although today's midwives provide care to women across the lifespan, including nonmaternity care such as family planning, gynecologic, and primary care services, historically nurse-midwifery practice was more limited. The first nurse-midwives in clinical practice primarily combined maternity care with traditional public health nursing services, but midwifery scope of practice has been evolving ever since.

Maternity Care During the Early Twentieth Century

When nurse-midwifery was introduced, most nurse-midwives in clinical practice cared for women only during pregnancy, labor, birth, and the puerperium.[35] During the first 2 decades of the twentieth century, inadequate maternity care was linked to the high rates of maternal and infant morbidity and mortality. During this period of increased interest in maternal and child health, the federal Children's Bureau was established (in 1912) and researchers began to gather evidence that conclusively linked high-quality prenatal care with reductions in maternal and infant mortality.[45]

From the earliest days of the establishment of prenatal care, the elements of nurse-midwifery–led prenatal care have remained remarkably consistent. Maternity Center Association prenatal care was described as including "instruction in healthful living. . . . The nurse-midwife helped each woman to evaluate her diet . . . on the basis of the recommended allowances of the National Research Council—and suggested ways to supplement deficiencies with foods acceptable to her and her family."[46(p29)]

Similarly, "Mothers' Classes" during the 1940s at the Catholic Maternity Institute in Santa Fe included discussions of "preparation of the body (physical and psychological changes); hygiene of pregnancy: diet, rest, clothing, cleanliness, sex relationships, varicose veins, backache, heartburn, breast enlargement, danger signals, need of medical care; . . . [and] preparation of husband, children . . . and supplies."[47(pp182-183)]

Public Health Services During the Early Twentieth Century

Midwifery has always had a strong link with public health. When nurse-midwifery was introduced in the United States, public health nurses were the logical choice to be prepared as nurse-midwives because public health nurses already included maternal–child health care as part of their services. Additionally, the National Organization for Public Health Nursing (NOPHN) was one of the first nursing organizations to recognize nurse-midwifery.[45] Public health nursing practice constituted a logical extension of some nurse-midwives' work because they were often practicing in areas of great medical need. For example, MCA public health nurses traveled throughout the project area, performing door-to-door case finding, assessing home environments of women who planned a home birth, and encouraging women to seek prenatal care. MCA public health nurses also coordinated with other community services that

pregnant women might seek, such as milk stations, settlement houses, and churches.

Like her MCA colleagues, Mary Breckinridge recognized soon after she founded the Frontier Nursing Service that the FNS would not be successful if it did not also provide comprehensive public health and general primary care services to its rural population.[48,49] An area of particular public health concern for FNS was parasite control and its corollary, sanitation. Worm infestations were rampant in children throughout the area and were a frequent cause of poor health. Slowly, the FNS nurses urged the mountain people to build sanitary toilets and chlorinate infected wells. Likewise, great emphasis was placed on vaccinations and other preventive services.[48] See **Figure 1-4**.

Meeting the Needs of Non-Childbearing Women: 1950s to the Present

By the 1950s, societal factors and scientific advances had converged, and nurse-midwives began to consider expanding their scope of practice. Nurse-midwives' forays into family planning began in 1958, when FNS nurse-midwives served as clinicians in a study of

combined oral contraceptive pills. Under the auspices of researcher John Rock's study, FNS nurses administered pills and incorporated care of study participants into their usual work. After the study was completed and the oral contraceptive pill was approved for use in the United States, the provision and management of birth control pills was integrated into the role of the FNS nurse-midwife. Shortly thereafter, the FNS nurse-midwives were taught to insert intrauterine devices and manage follow-up care.[50]

Although the FNS nurse-midwives were able to expand their role to include family planning services, the addition of family planning care to midwifery practice in other areas was more difficult. Helen Varney Burst recalled as a Yale University nurse-midwifery student in 1962 that:

> *. . . family planning consisted of surreptitiously passing to a woman, literally under the bed covers, a Planned Parenthood pamphlet with the address of the clinic nearest her home circled. I was told that it was "against policy" or "illegal" to disseminate family planning information, much less provide contraceptive methods, in the New York City municipal hospitals.*[51(p527)]

That situation changed in 1965 with the work of Shirley Okrent, a nurse-midwifery student at Kings County Hospital/State University of New York Downstate Medical Center. Okrent was reported to her supervisors for talking with her postpartum patients about family planning in spite of the topic not being part of nurse-midwifery education curriculum or recognized within the nurse-midwifery scope of practice at that time. Fortunately for Okrent, the chair of the Department of Obstetrics and Gynecology had been searching for a nurse-midwife to staff a family planning clinic. During Okrent's remaining education and after her graduation, she learned about intrauterine device placement, diaphragm fitting, and oral contraceptive pill counseling and prescription.[51] Okrent published accounts of her experiences in 1966 and 1970 issues of the *Bulletin of the American College of Nurse-Midwifery*.[52,53] She also published clinical guides on oral contraception, intrauterine devices, and the diaphragm.[54,55] At the time, Okrent's work in expanding midwifery scope of practice met with mixed reviews. Some nurse-midwives resolutely insisted that nurse-midwifery care should end at the 6-week postpartum visit; others opposed any family planning except abstinence; and some worried that family planning work would include abortions.[51]

By the late 1970s, nurse-midwifery scope of practice had expanded further to include other aspects of gynecologic care, initially called interconception care. The 1978 ACNM definition of nurse-midwifery practice added "and/or gynecologically" to its list of management areas. The first edition of Varney's textbook, *Nurse-Midwifery*, in 1980, included one section titled "Management of the Interconceptional Period" and described care during that period as "the primary health care of women who are between menarche and menopause as it relates to the female reproductive system [including] women who not only are not pregnant but who may or may not wish to be pregnant."[51(p528)]

During the 1980s and 1990s, nurse-midwives began screening for gynecologic problems and offering care for women who had sexually transmitted diseases.[49] Midwives also added the care of perimenopausal and menopausal women because, as Mary Barger pointed out, "As the

women whose babies midwives delivered and provided with preventive gynecology care continued their lives, they wanted to keep on seeing midwives."[56(p88)]

During the 1990s, increasing numbers of midwives began providing primary health care to women, particularly in rural and underserved areas. A 1993 ACNM survey found that nurse-midwives were managing acute and chronic conditions such as bronchitis, asthma, colds, ear infections, anemia, mild hypertension, diarrhea, and dermatitis. Nurse-midwives were also addressing physical, sexual, and emotional abuse, as well as drug and alcohol dependence.[57] Mary Ann Shah, the editor of the *Journal of Nurse-Midwifery*, expressed support for the ACNM's 1992 position statement that nurse-midwives are primary care providers. Pointing to the high prevalence of heart disease in women as well as women being "lulled into a false sense of security by the reassurance that their breasts and reproductive organs remain cancer free," Shah argued for nurse-midwives "to make absolutely certain that we are competent to provide the most comprehensive primary care possible."[58(pp185,187)]

Systematic Processes for Defining and Expanding Scope of Practice

Throughout the history of the profession, nurse-midwives have developed systematic processes to define and evaluate their scope of practice and thoughtfully add new elements. Since 1955, the ACNM has served as the central authority charged with defining nurse-midwifery practice. In each update of the ACNM Definition of Nurse-Midwifery Practice, the scope of practice is defined more extensively and includes more elements. For example, the 1961 version stated, "Nurse-midwifery practice is an extension of nursing practice into the areas of management of care of mothers and babies throughout the maternity cycle so long as progress meets criteria accepted as normal." Later versions eliminated the criteria that women be "essentially normal" in recognition that midwifery practice had expanded into care of women with some complications and comorbid conditions. The current definition recognizes certified midwives as well as certified nurse-midwives.

Recognizing that midwifery practice is ever evolving, ACNM developed *Standards for the Evaluation of Nurse-Midwifery Procedural Functions* in 1972.[59] These guidelines formed a structure for nurse-midwives to use in assessing appropriateness of new practice elements. This process was updated in 1992 and published as *Guidelines for Incorporation of New Procedures into Nurse-Midwifery Practice*, which now can be found in the *Standards for the Practice of Midwifery.*

During the 1980s and 1990s, interest in "advanced" skills continued to grow. Surveys of ACNM members found that nurse-midwives were performing procedures that had not been part of their basic education, including placement of fetal scalp electrodes and intrauterine pressure catheters, repair of third- and fourth-degree lacerations, circumcision, use of vacuum extractors and forceps, manual removal of the placenta, paracervical blocks, ultrasonography, colposcopy, endometrial biopsy, external cephalic version, and being first assistant at a cesarean birth.[49] In 1993, a special issue of the *Journal of Nurse-Midwifery* provided, for the first time, a "comprehensive look at nurse-midwifery practice beyond its traditional boundaries."[60(p10S)] The issue included articles and a "home study program" dealing with circumcision, endometrial biopsy, third-trimester ultrasound, amnioinfusion, external cephalic

version, vacuum extraction, subdermal contraceptive implants, and fetal scalp blood sampling.

In spite of some nurse-midwives' enthusiasm for expanding their scope of practice through the addition of advanced skills, midwives have always grappled with defining the boundaries of the profession.[61,62]

Summary

The scope of practice of the earliest nurse-midwives primarily entailed maternity care, including the relatively new prenatal care process. Some early nurse-midwives included public health care in their services to meet the needs of the populations they served. Gradually, to continue to meet women's needs, family planning, gynecologic care, primary care, and "advanced skills" became part of midwives' scope of practice. Throughout this evolution, a systematic process for modifying the scope of practice has guided the profession.

Caring for Underserved Populations

Although the scope of midwifery practice has expanded over the past century, many aspects of midwifery care remain unchanged—particularly the focus on caring for women and families with unique health needs resulting from lack of access to care and other social, geographic, ethnic, or other factors. In fact, nurse-midwifery in the United States is firmly rooted in caring for members of underserved populations. The founders of the first nurse-midwifery services, including the Frontier Nursing Service, the Maternity Center Association, and the Catholic Maternity Institute, established these services as targeted strategies to serve the needs of some of the most underserved people of the day. Studies have consistently shown positive health outcomes of midwifery care, even in populations whose socioeconomic factors are often associated with poorer outcomes.

Nurse-Midwifery Care of Underserved Populations in the Early Twentieth Century

In New York City, the MCA served poor, urban-dwelling women, many of whom lived in cold-water tenement flats and were undernourished, lacked social support, and of high parity. MCA served a predominantly African American and Puerto Rican clientele, groups that struggled with high rates of unemployment, housing discrimination, and workplace exploitation. Many MCA patients were unable to pay the $5 fee the service charged to cover prenatal, labor and birth, and postpartum care.[20]

When Mary Breckinridge decided to establish the Frontier Nursing Service in southeastern Kentucky to provide maternity and general nursing care to thousands of mountain residents, she chose this geographic region because of the area's isolation, high rate of poverty, lack of healthcare options, and poor health outcomes. According to a 1931 American Medical Association publication:

> *The Frontier Nursing Service has set out to provide nursing, public health service and midwifery under medical direction . . . for the remotest sections of the southern mountains. Its work began . . . with two nurse-midwives in a remote Kentucky county in which . . . there was no resident physician for a population of 10,000 people. . . . The country is a veritable frontier—no railroads, no automobile roads, no bridges over its rivers and creeks. . . . Land usable for farming is so scant that the people are very poor.*[63](p633)

Another early nurse-midwifery service established to meet the needs of a underserved population was the Catholic Maternity Institute. In the early 1900s, New Mexico's population was predominantly rural, with fewer than 3 people per square mile in New Mexico compared to nearly 31 people per square mile nationwide.[64] New Mexico was the last state in the nation to establish a state health department, and infant mortality rates in New Mexico were among the highest in the nation when the Catholic Maternity Institute was founded. Medical care was less available to New Mexicans than to residents of other states, with about half the number of

physicians per person.[64]

The Medical Mission Sisters—a Catholic order of nurses, physicians, and other healthcare providers—was organized to provide medical services internationally but was available for service in the United States at that time due to World War II travel restrictions. In response to the great needs in rural New Mexico and at the request of the Archbishop of Santa Fe, the sisters established the Catholic Maternity Institute there in 1944. Sister Theophane Shoemaker, one of the founding members of the Catholic Maternity Institute, described their approach, embodying the ideals of providing what was needed to communities of great need:

> *. . . we became an integral part of the community of Santa Fe. . . . we became acquainted with the families . . . visited every health and social agency and met their officers and staff members. We went on home visits with the public health nurse as a means of learning the importance of tiny alleys and the humble homes to which they lead. We talked with hundreds of mothers . . . and from them we learned that the people are for the most part very poor, uneducated, proud of their culture, and sensitive to protect it. They are willing to accept good care but unwilling to be served by professionals who may not be sympathetic.*[65(p645)]

Today, midwives continue to care for women who represent a wide range of underserved populations. Some of these populations include racial and ethnic minorities; pregnant adolescents; immigrants; impoverished women; residents of Indian reservations; lesbian, gay, bisexual, transgender, and queer (LGBTQ) persons; and low-income and uninsured persons who receive care in Federally Qualified Health Centers (FQHCs). One commonality between these groups is a lesser degree of access to healthcare services compared to the general population. The work of innumerable midwives who have cared for underserved populations is illustrated in the following exemplars.

Race, Ethnicity, and Culture

Midwives have always cared for women who come from diverse cultures, and they continue to play an important role in providing healthcare services to women in racial and ethnic minority groups. A 1994 *Journal of Nurse-Midwifery* article reported the results of more than 30,000 nurse-midwife–attended births between 1981 and 1992 in the in-hospital birth center at the University of Southern California Women's Hospital in Los Angeles. Service staff members cared for a largely Hispanic, low-income population and recorded excellent outcomes, with successes attributed to a cooperative system of interprofessional care that could serve as a model for caring for low-income, minority women and infants.[66] Studies conducted as recently as the late 1990s and early 2000s show that nurse-midwives are still caring for women who belong to many diverse populations and that nurse-midwives were more likely than physicians to care for women from minority populations.[67]

It is important to note that the midwifery workforce has never matched the racial and ethnic composition of midwifery clients. In 1981, Betty Watts Carrington wrote of her concern with "this very low representation of ethnic minorities in American nurse-midwifery," citing, among

other considerations, the *difficulty* "for nonminority healthcare providers to be sensitive to and identify subtle cultural traits and lifestyles that adversely affect minority health."[68(p1)] Carrington voiced frustration about the lack of progress in minority recruitment of nurse-midwives and issued a plea for the profession to "make a greater effort to see that [nurse-midwifery] represents the cultural and ethnic richness of American society."[68(p2)] In spite of work within the profession to develop a more diversified workforce during the 1980s and 1990s, Holly Powell Kennedy and colleagues' "Voices of Diversity in Midwifery Study" in 2006 indicated that midwifery clients were still significantly more racially and ethnically diverse than the midwifery workforce.[69] This is an important focus for the ongoing evolution of the midwifery profession today.

Immigration

Midwives have often served as healthcare providers for immigrant women, and numerous published reports have documented the effectiveness and cultural appropriateness of that care. One exemplary report is that of Kathleen Morrow, who in 1986 described the interplay between midwifery care and birthing customs of Hmong people in California. Morrow concluded:

> *In listening to the Hmong, I became aware of the important role of childbirth traditions in maintaining physical and mental well-being. As nurse-midwives, we can actively assist people by accepting and incorporating their customs whenever possible into their health care. This is only a beginning, and I encourage other CNMs to explore the cultural implications in healing. Technology cannot replace the emotional and spiritual benefit accomplished through maintaining these customs.*[70(p288)]

Native Populations

Native populations and residents of reservations often experience challenging circumstances related to housing, sanitation, employment rates, nutrition, and transportation; midwives have worked to ease native peoples' healthcare difficulties for many years. Nurse-midwifery care with native populations has contributed to improved maternal and neonatal health outcomes and enhanced access to care, including a greater number of prenatal and postpartum visits and nutrition counseling.[71]

Beginning in 1969, Carol Milligan provided midwifery care as an Indian Health Service employee in Bethel, Alaska—a community with the nation's highest infant mortality rate that was so remote that it was accessible only by boat or plane.[8] In the early 1970s, nurse-midwives cared for Navajo women in Fort Defiance, Arizona. They included Hazel Canfield, the first Navajo midwife, and Ursula Knoki-Wilson, the daughter of a traditional midwife, who received the American College of Obstetricians and Gynecologists' 2017 William H.J. Haffner American Indian/Alaska Native Women's Health Award for her work in health care and advancing cultural awareness.

A 2008 ACNM publication described midwives' contributions to the Indian Health Service.[72] At that time, nurse-midwives provided comprehensive care in nine Indian Health Service regions, demonstrating excellent maternal and neonatal statistics. Nurse-midwives' work in this setting is geared toward meeting the unique needs of their communities. For example, the Chinle Comprehensive Health Care Facility provides "midwifery care that is culturally appropriate for the Navajo women and families they serve . . . the Midwifery Service has developed its own educational materials that present information that is grounded in Navajo culture."[72(p2)]

Socioeconomic Risks

A demonstration project in an impoverished agricultural community in California, Madera County, between 1960 and 1963 is an important and often-cited illustration of the effect of midwifery care in populations of women who have socioeconomic risks for adverse health outcomes. At the time, this area suffered from critical shortages of physicians; large numbers of migrant farmworkers in Madera County received late or no prenatal care and gave birth unattended by a physician. Because midwifery was illegal in California at that time, a special law authorizing midwifery practice allowed nurse-midwives to manage women with normal pregnancies, labors, and births. By the end of the project, CNMs were attending 78% of hospital births and access to care had improved dramatically in Madera County. Rates of premature births dropped from 11% to 6.4%, and neonatal mortality declined from 24/1000 live births to 10.3/1000 live births.[73,74] After the program ended and the midwives no longer provided care, a follow-up study showed immediate and significant increases in the rates of premature birth, neonatal mortality, and percentage of women who received no prenatal care. Nearby services did not see such changes, supporting the conclusion that the discontinuation of the nurse-midwifery program was responsible for the worsening of access and outcomes.[73,74] Recognizing the value of this work, state officials in California identified three essential components of the Madera County OB Access Program—nutrition counseling, psychosocial evaluation, and health education—and adopted these three aspects of midwifery practice as required elements in California's Medicaid obstetric service program. They remain required elements today.

The nurse-midwifery care of poor urban women at Grady Memorial Hospital in Atlanta, Georgia, was studied by Elizabeth Sharp and Lizabeth Lewis in 1984. Maternity patients were vulnerable to poor health outcomes due to social and economic circumstances, high parity, ages at the extremes of childbearing years, and race. Nevertheless, Sharp and Lewis concluded that "nurse-midwifery care can be integrated into a large tertiary level obstetric service retaining the philosophic stance of comprehensive care. . . . Practices related to patient options . . . are modifiable in a high technology setting."[75(p364)]

Lesbian, Gay, Bisexual, Transgender, and Queer Persons

LGBTQ persons are at increased risk for poor health outcomes as compared with non-LGBTQ persons. Midwives' commitment to meeting the needs of gender minorities can be found in

published reports dating to the 1980s. In 1984, nurse-midwives Eileen Olesker and Linda Walsh reported the results of their study of lesbians who had become pregnant. The researchers were interested in documenting the needs and perceptions of lesbians in order to improve nurse-midwives' knowledge and sensitivity to the needs of this population. The findings revealed that participants wanted healthcare providers to be knowledgeable about health needs unique to the population, as well as to demonstrate open and supportive attitudes.[76] Another midwifery study of lesbian mothers' experiences with health revealed that women who chose midwifery care reported higher levels of support from and comfort with their provider, as compared to women who chose physician care.[77]

More recently, midwives have demonstrated their commitment to serving the LGBTQ population by revising the ACNM's Core Competencies for Basic Midwifery Practice in 2012 to include a requirement to apply "knowledge, skills, and abilities, including in gynecologic care that include . . . human sexuality, including . . . gender identities and roles, sexual orientation . . . counseling, clinical interventions, and/or referral for sexual and gender concerns."[78] Moreover, the *Journal of Midwifery & Women's Health* has published several articles over the last several years aimed at enhancing midwives' knowledge and skills in caring for persons who identify as LGBTQ.[79]

Women Served by Federally Funded Health Centers

Federally funded health centers provide comprehensive primary care, with special emphasis on underserved populations, including migrant workers, homeless persons, residents of public housing, and others in need of affordable health care.[80] A 2010 ACNM publication provides details about 16 FQHCs that offer midwifery care.[81] Each center demonstrates midwifery principles of caring for underserved populations in culturally appropriate ways.

Summary

Since the profession's inception, midwives have cared for members of underserved populations, beginning with women and families in isolated and mountainous regions of Kentucky, impoverished women in crowded tenements of New York City, and women in rural and medically underserved New Mexico. Throughout the profession's history, midwives have continued to serve medically at-risk populations, and research has shown that midwifery care has provided benefits to those whom the profession serves.

Place of Birth

Having explored midwifery history through the lens of the populations midwives serve, we now consider where midwifery-attended births have taken place. Although most nurse-midwife–attended births occurred in women's homes in the earliest years, larger societal trends have caused the place of birth to shift over the years. Regardless of where births have taken place, midwives have worked to keep the woman at the center of the birth experience.

Births in Women's Homes

Prior to the 1950s, nearly all women gave birth at home, and nurse-midwives attended women at home. As the place of birth then largely changed from home to hospital, nurse-midwives worked diligently over the years to obtain hospital privileges so that they could continue to remain "with woman" during labor and birth.

The earliest nurse-midwifery services in the United States were created as home birth services and continued in this fashion for decades, with the majority of births taking place in women's homes. During the 26 years that the Maternity Center Association/Lobenstine Clinic provided clinical services (1932–1958), clinic staff attended a total of 7099 births; 6116 of these births took place in women's homes. Outcomes of these home births were excellent. The maternal mortality rate of the clinic was 0.9 per 1000 live births, as contrasted with a maternal death rate of 10.4 per 1000 live births for that geographic district as a whole, and 1.2 per 1000 live births for a leading hospital in New York City at that time.[82]

Likewise, in rural southeastern Kentucky, the vast majority of births attended by Frontier Nursing Service nurse-midwives between 1925 and 1950 occurred in their patients' mountain homes. As with the Maternity Center Association, outcomes of these home births were outstanding, with lower maternal and neonatal mortality rates than in other areas of the country, despite the local population's socioeconomic and health-related risk factors.[83]

In the rural Santa Fe, New Mexico, area, the staff of the Catholic Maternity Institute also attended nearly all births in homes between the service's inception in 1944 and 1950. Indeed, home birth was the sisters' ideal, economically and spiritually. During mothers' classes, the staff emphasized: "Home delivery is good and proper thing (besides being cheaper). Not only the Birthday but birthplace is important. Bethlehem's stable honored world over."[84(p156)] Recounting her experiences attending births in her patients' homes, nurse-midwife Sister Catherine Shean said:

> *I think one of the most beautiful [aspects] for me was when you were in the home and the baby was born and . . . the mother had been cleaned up and she was ready to receive the baby . . . many times the other younger children were invited in to meet the baby. . . . We had the tradition in our midwifery service that when we finished with the mother . . . we would gather together the family and the husband and we would pray with them before we left, thanking God for this new life and for all the help that He had given to us.*[84(pp156-157)]

Although the Catholic Maternity Institute was founded as a home birth service, within 2 years of the service's inception, CMI staff began offering women the choice of giving birth in their homes or in a small freestanding building, La Casita, near CMI's main building. La Casita births met a number of practical needs, including close proximity to the hospital in the event of complications, an increased number of clinical experiences for student nurse-midwives, and more efficient use of the midwives' time, given the long and difficult travel requirements to reach patients' homes. See **Figure 1-5**.

Shift to Hospital Birth, 1930s to 1950s

Major shifts in national birth trends occurred during the 1930s and 1940s. In 1932, more than 60% of births took place at home; by 1950, however, 88% of births took place in hospitals.[45] A confluence of factors contributed to this change, including explosive growth in the number of hospital beds and the increased number of people using health insurance. Another factor was the widespread acceptance of maternity care practices that required hospitalization, including analgesic and amnesic medications to manage labor pain, and the use of forceps and

episiotomies. Importantly, too, health experts in that era credited the improvements in maternal and infant mortality rates to the increased percentage of hospital (physician-attended) births.

At midcentury, nurse-midwives maintained their focus on meeting women's needs, using established elements of the midwifery model of care. They made concerted efforts to bring consumer advocacy and family-centered maternity care to hospitals. Although many women and their caregivers were no longer in the home at the time of birth, nurse-midwives' leadership was key in promoting rooming-in and breastfeeding; studying the effects of natural (prepared) childbirth and family-centered supportive care on a woman's prenatal, intrapartum, and postpartum experience; and including fathers or significant others in hospital labor and delivery rooms.[85]

Although it is unclear who first used the phrase "family-centered maternity care," MCA director Hazel Corbin is generally credited with widely promoting the concept. Corbin highlighted the need to involve a woman's family, so as to counteract the negative effects a hospital birth experience could have on the development of the family unit. Nurse-midwife and MCA graduate Kate Hyder contributed to development of the United States' first rooming-in unit at Grace–New Haven Community Hospital in the mid-1940s.[7] When nurse-midwife and MCA graduate Ernestine Wiedenbach published a nursing textbook, *Family-Centered Maternity Nursing*, in 1958, she reframed the art and science of obstetric nursing and inspired a generation of nurses to seek midwifery education.[86]

1960s: Resurgence of Home Birth

During the late 1950s and the 1960s, an increasing number of women and families voiced dissatisfaction with the hospital birth status quo: Hospital staff often separated families during labor and birth; women underwent routine enemas, vulvar shaving, and episiotomies; and they gave birth with their legs strapped into stirrups. Finding the hospital environment to be too confining and disempowering, some consumers, midwives, and physicians began to reconsider home birth. During the 1970s, fueled by feminism, counterculture ideals, and the women's health movement, consumer demand for home birth grew.

The consumer dissatisfaction with professional health care contributed to increased interest in midwives who were often characterized as "lay midwives." These midwives, with varying educational backgrounds, offered home birth services. Lay midwifery suffered from its own challenges as an unregulated group during this era. The educational preparation of non-nurse-midwives during the 1970s and 1980s was highly variable. Lay midwives and their advocates worked to resolve questions regarding the desirability of formal education, standards, credentialing, and regulation. A number of groups and organizations were founded during the 1970s to attempt to unite supporters of lay midwifery and home birth, including the National Association of Parents and Professionals for Safe Alternatives in Childbirth (NAPSAC), Home Oriented Maternity Experience (HOME), Association of Childbirth at Home International (ACHI), and National Midwives Association (NMA). Existing organizations, such as the International Childbirth Education Association (ICEA) and La Leche League, added their support. The first national meeting of lay midwives took place in 1977 in El Paso, Texas.[7]

In spite of increasing consumer demand for home birth, nurse-midwives' professional consensus on birth at home was slow to develop. Nurse-midwives who chose to provide home birth services in the early 1970s did so without support from ACNM. A statement on home births, adopted in 1973 and published in a 1975 *Journal of Nurse-Midwifery*, was critical of home birth: "ACNM considers the hospital or officially approved maternity home as the site for childbirth because of the distinct advantage to the welfare of mother and child."[87(p15)] Some ACNM members voiced opposition to this statement, citing a lack of supporting research. Additional discussion ensued and, in 1980, the ACNM published a statement on practice settings that acknowledged the home as an acceptable practice location.

During the 1990s, ACNM established a formal structure to address the needs of midwives providing home birth services.[88] Today home birth is strongly supported by ACNM within evidence-based guidelines that address safety, and appropriate candidates for care in this setting as reviewed in more detail in the *Birth in the Home and Birth Center* chapter.

1970s: The Birth Center Movement

While some nurse-midwives, consumers, and non-nurse-midwives viewed home birth as the best alternative to hospital birth for selected low-risk women, others became interested in a different option—the birth center. Building on the foundation established by La Casita, the Catholic Maternity Institute's freestanding birth center in Santa Fe, which operated from 1946 through 1969,[84] the modern birth center movement developed during the 1970s and 1980s. The first freestanding birth center of that era opened in 1975: Maternity Center Association's demonstration model, the Childbearing Center (CbC). MCA staff opened the CbC after they "detected a new determination in some childbearing couples . . . to give birth out of hospital." Birth center pioneer and nurse-midwife Ruth Lubic describes the reason that couples desired out-of-hospital birth:

> . . . *hospitals—or rather the professionals functioning within them—had grown* increasingly insensitive to the need of members of human families for each other's pres*ence in times of crisis and celebration, particularly during and surrounding childbirth. This attitude on the part of medical professionals may have been a side-effect of their almost religious fervor to improve rates of maternal and infant survival.*[89(p225)]

The birth center movement grew quickly, and birth center advocates diligently studied and reported birth center care outcomes. In 1981, MCA funded the first national study of birth center outcomes in 14 centers. Several important publications followed, including two landmark studies: the National Birth Center Study (1985–1987), published in the *New England Journal of Medicine*, and the San Diego Birth Center Study (1994–1996), published in the *American Journal of Public Health*.[90,91] These studies demonstrated that birth center care is safe, effective, satisfying, and cost-effective. The National Birth Center Study II, published in 2013, again demonstrated the safety of the birth center model. This study, led by nurse-midwives Susan Stapleton and Cara Osborne, included more than 15,000 women.[92]

Organizations composed of dedicated professionals helped the birth center movement to succeed. Over the years, the MCA's Cooperative Birth Center Network (CBCN), founded in 1981, evolved to be known as the National Association of Childbearing Centers (NACC) in 1983. In 2005, this organization changed its name to become the American Association of Birth Centers (AABC). AABC's many contributions to the birth center movement include articulating eligibility criteria for birth center care, developing national quality standards, fostering state licensure, developing clinical position statements, securing liability insurance, promoting reimbursement, establishing accreditation mechanisms, and participating in crucial birth center outcomes studies.

Summary

The earliest nurse-midwives attended births almost exclusively in women's homes. As the twentieth century progressed, larger societal influences led more women to choose hospital birth; in turn, nurse-midwives sought opportunities to serve women in that setting. In the 1960s and beyond, women began to demand more control and a less medically focused birth experience. Consequently, home birth experienced a resurgence, and the same factors led to increasing interest in birth center care.

Nurse-Midwife/Physician Collaboration: Opportunities and Challenges

Regardless of whether nurse-midwives have attended births in women's homes, birth centers, or hospitals, collaboration with physician colleagues has been crucial. The earliest nurse-midwives actively worked to avoid conflicts with physicians. Today midwives and physicians optimally work as members of a team, although the midwife–physician relationship has evolved over the years as both professions matured.

Early Models of Successful Collaboration

The new profession of nurse-midwifery emerged from the social and cultural context of the "midwife problem." From the earliest days of this profession, several services demonstrated successful models of physician support and collaborative care utilizing nurse-midwives. One supportive physician was the prominent and influential Ralph Lobenstine, whose work with the Maternity Center Association in New York City was crucial to the MCA's early successes. In a 1939 *American Journal of Nursing* article, Hattie Hemschemeyer described in detail the careful collaboration between MCA nurse-midwives and physicians, and identified the ways in which that collaboration resulted in healthier mothers and babies.[93]

In 1925, when the Frontier Nursing Service was founded in Kentucky, the legal authority for practice stemmed from the clearly articulated support of FNS's physician collaborators. According to the FNS's statement of purpose, midwives were expected to work "under supervision, in compliance with the regulations for midwives of the State Board of Health and the law governing the Registration of Nurses in Kentucky; and in cooperation with the nearest medical service."[49(pp523-524)] Moreover, the FNS hired a physician as medical director, convened a Medical Advisory Committee, and created an extensive medical routine (protocols).[48]

At the Catholic Maternity Institute, the nurse-midwives and their collaborating physician developed and maintained a strong and mutually respectful relationship. Sister Theophane Shoemaker, the CMI director, wrote in 1946 of the support of the medical director:

> *One of the greatest contributors to our early success and to the progress of our work, was Nancy Campbell, M.D., an obstetrician, who from the beginning has been the medical director of our program. She is convinced of* the special contribution nurses trained in midwifery have to offer. . . . Over and over again she told patients about our work and said to them: "Go to the Sisters, because they are trained as nurses and as mid *wives to give good care . . . the nurse-midwives can give better delivery care because they can give more time throughout labor and delivery than I or any other physician can afford to give."*[65(pp645-646)]

Effects of Physician Shortages in the Mid-Twentieth Century

At midcentury, members of the medical community expressed growing interest in nurse-

midwife/physician collaboration, particularly as it affected looming shortages in the maternity care workforce. Concerned about the effects of the post–World War II baby boom, an obstetrician wrote in a 1959 *Bulletin of the American College of Nurse-Midwifery*:

> *. . . the American economy is expanding and with this expansion goes a great increase in population: more babies will be born but there will not be a commensurate increase in physicians and therefore other birth attendants will be needed; and nurse-midwives are the logical people to fill this role.*[94(p9)]

Additionally, nurse-midwives were becoming more visible in some physician-dominated arenas. For example, in the mid-1950s, nurse-midwifery programs opened within university teaching centers at Columbia, Johns Hopkins, and Yale.[95]

Control of Nurse-Midwifery Training and Practice in the 1960s and 1970s

Although some obstetricians supported nurse-midwifery in concept, many physicians believed that obstetricians should control the training and practice of nurse-midwives. Physician John Whitridge wrote of his vision of how best to use the modern nurse-midwife in the *Bulletin of the American College of Nurse-Midwifery* in 1960:

> *Working in cooperation with and under the supervision of physicians, the nurse-midwife can spare the physician many long hours of work for which his special skills are not always required. . . . The nurse-midwife is trained and accustomed to working under medical supervision and would be most unhappy as an independent practitioner of midwifery.*[95(p33)]

In fact, heated debates about this topic occurred within the American College of Obstetricians and Gynecologists (ACOG) throughout the 1960s. In 1959, ACOG convened a Committee on Obstetrical Assistants to study the role of nurse-midwifery in the United States. Debates among committee members ranged from whether ACOG would support nurse-midwifery in general, to committee members' opinions about the name "nurse-midwife." In 1971, the Committee on Obstetrical Assistants became the Committee on Professional Personnel and recommended the adoption of the *Joint Statement on Maternity Care* that the American College of Nurse-Midwives had approved.[96]

This official ACOG recognition of nurse-midwives represented an important step forward in professional recognition but it did not equate to full professional autonomy for nurse-midwives. Indeed, the *Joint Statement* specified that "The cooperative efforts of teams of physicians, nurse-midwives, obstetric registered nurses and other health personnel will be directed by a qualified obstetrician-gynecologist."[96(p22)]

Successful Collaboration Models in the 1960s and 1970s

During the 1960s and 1970s, a number of nurse-midwife/physician interdisciplinary teams demonstrated that nurse-midwife/physician collaboration was a successful model. One

example was the Madera County Demonstration Program in California. Publishing their results in the *American Journal of Obstetrics and Gynecology*, Levy and colleagues argued that nurse-midwives not only relieved a maternity care provider shortage in Madera County, but the collaborative approach of physicians and nurse-midwives also drastically improved maternal and neonatal health indices.[73] Similarly, a maternity care team in Holmes County, Mississippi, demonstrated that infant mortality could be halved by including nurse-midwives and physicians in the same maternity care team.[97] When nurse-midwife Marie Meglen spoke at the 1971 ACOG meeting and described her experiences in the Holmes County service, she implored attendees—most of whom were physicians—to include nurse-midwives in solving maternity care challenges:

> *. . . by using each member of the team to do only those things for which he or she is best prepared, we will be able to provide better care for more patients and, in the long run, change the standard of maternal and infant health care in our area. We have learned a great deal in our first two years in Mississippi, which I would like to pass on to you in hopes that it might expedite your efforts if you should want to make use of nurse-midwives.*[98(p67)]

Similarly, a service in Springfield, Ohio, successfully incorporated nurse-midwives into the Maternal Health Service. Physician John Burnett published information about his experiences in Springfield in *Obstetrics and Gynecology*, increasing awareness among obstetricians about "matching talents with needs" within the obstetrics service and arguing that "the nurse-midwife has demonstrated her ability to join physicians in the practice of total maternity cycle care."[99(p719)]

Increased Consumer Demand for Midwifery: 1970s to the Present

Societal shifts during the 1960s and 1970s, including feminism and the consumer movement, created more middle-class demand for nurse-midwifery. Earlier in the profession's history, nurse-midwives had primarily cared for women from lower-socioeconomic groups and in areas in which few physicians wanted to practice; during the 1970s, however, more middle-class women who could pay for maternity care wanted midwives. In fact, the 1976–1977 survey by the American College of Nurse-Midwives reported that approximately 26% of all nurse-midwives practicing nurse-midwifery worked in some form of private practice arrangement.[100]

By the 1990s, professional autonomy for nurse-midwives had become more established. The ACNM's 1992 revision of the definition of nurse-midwifery practice removed the modifier of "essentially normal" to describe the populations served by nurse-midwives, thereby expanding the scope of "independent management," and removed any reference to medically directed teams. Throughout the 1990s, the *Journal of Nurse-Midwifery* published a number of articles and editorials to provide nurse-midwives with an armamentarium of validation of their experiences, encouragement to continue advocating for themselves, and resources with which to build their knowledge about collaborative practice.[101-103]

Midwife/physician collaboration continues to evolve today. In 2002, ACOG and ACNM published a revised version of the *Joint Statement of Practice Relations Between Obstetrician-Gynecologists and Certified Nurse-Midwives/Certified Midwives* that, for the first time, made no mention of physician supervision or of unequal professional standing between midwives and physicians. The 2011 *Joint Statement* update continued to codify the intention to move forward with mutual respect and collaborative relationships.[104] Unfortunately, there are still some areas where physicians and certified nurse-midwives or certified midwives wish to work collaboratively but are challenged by outdated legislation and problems obtaining reimbursement.

Summary

The complicated relationship between midwives and physicians has been influenced by successful models of collaboration as well as by periods of conflict regarding professional autonomy and competition. In spite of conflicts, midwives and physicians share a common goal of safeguarding the health and safety of women and families. The work toward optimal collaboration to reach that goal continues.

Documenting the Outcomes of Midwifery Care and Midwifery Research

Many midwifery scholars, researchers, and clinicians have used the carefully collected and documented evidence of the excellent outcomes of midwifery care. This research began with the earliest nurse-midwifery service and has continued throughout the profession's history.

Early Nurse-Midwives' Documentation of Outcomes

The Maternity Center Association's work in New York City provides an important example of nurse-midwives' documentation of the outcomes of their care. Data analysis of MCA's comprehensive maternity care system indicates that MCA-provided care resulted in significantly improved rates of maternal, fetal, and neonatal deaths. These and other data, such as method of delivery, total registrations, location of birth and type of birth attendant, patient gravidity, complication rates, and patient and nurse-midwife satisfaction, were reported in meticulous detail in a 1955 MCA publication, *Twenty Years of Nurse-Midwifery, 1933–1953*.[46]

Importantly, the MCA's emphasis on documenting outcomes of safe care during those first 20 years did not overshadow the heart of midwifery care. Near the end of the 20-year report, the authors praised the progress in decreasing mortality rates but lamented that, nationwide, "*too little attention [has been] paid to the social and emotional aspects of childbearing and their influence on family life. The nurse-midwife is helping to restore the emphasis on patient-centered care and total health of mother and child.*"[46(p115)]

From the start of her work in Kentucky, Frontier Nursing Service founder Mary Breckinridge prioritized the collection and use of data to guide leadership decisions. Speaking to the significance of data and its iterative value for improving an organization, Breckinridge wrote, "Research is a continuing thing. As one acts, one gets an insight of what is best for the next action."[48(p159)] Indeed, Breckinridge recognized that the first task was to accurately define the baseline with which her service's work would be compared. Breckinridge described the evolution of the research process one year after the founding of the service:

> *Leslie is a laboratory, our field of research. . . . We ask ourselves questions like these: Will our maternal and infant death-rate in rural sections of Kentucky be lowered by this system of nurse-midwives to figures comparable with those of the Old World? What area and population can be served by each nurse, combining midwifery with generalized public health nurses? . . . We are keeping very exact daily records in order to answer this. What will the cost be? . . . Will the people accept this service? . . . Can the service extend indefinitely with nurses only? . . . Time will tell.*[105(p47)]

And time did tell, showing that the work of Breckinridge and her nurses improved outcomes for mothers, babies, and families in the mountains of Kentucky. After developing and implementing a comprehensive record system, the FNS staff gathered data using a statistical

system set up by the Carnegie Corporation; the results were then analyzed by statisticians from the Metropolitan Life Insurance Company. These findings, reported for each series of 1000 pregnancies of FNS patients, provided some of the first statistical evidence of the safety and effectiveness of nurse-midwifery care in the United States. "The Summary of the Tenth Thousand Confinement Records of the Frontier Nursing Service," written by Metropolitan Life Insurance Company staff, published in a 1958 FNS *Quarterly Bulletin*, and reprinted in a 1960 *Bulletin of the American College of Nurse-Midwifery*, is considered to be a seminal study—one of the most important studies demonstrating exemplary midwifery practice.[83] Although the FNS nurse-midwives faced treacherous mountain terrain, severe weather conditions, nonexistent roads, a lack of electricity and plumbing, and impoverished and poorly nourished patients, their work made a real difference. The maternal death rate of 12 per 10,000 live births for the total period during the first 30 years of the service's existence was dramatically lower than the national maternal mortality rate. In the United States as a whole, the maternal mortality rate was 66.1 per 10,000 live births in 1931. Although the national maternal mortality rate declined to 8.3 per 10,000 live births in 1950, for much of the period between the start of FNS and 1950, the incidence of death secondary to a childbirth-related cause for women cared for by FNS midwives was much lower than that of their peers across the nation.[48,83]

ACNM's Leadership and Support for Research: 1950s to the Present

As nurse-midwifery matured as a profession, and its professional organization mirrored that increasing sophistication, increasing support for research became evident. One of the initial objectives of the American College of Nurse-Midwifery was "to promote research and develop literature in the field of nurse-midwifery."[29] The ACNM's Research and Statistics Committee provided leadership and guidance in documenting midwifery practice and research. As early as 1956, just one year after the ACNM's incorporation, the organization surveyed nurse-midwives about research and board members discussed how to manage data. The results indicated that, not only were ACNM leaders interested in documenting midwifery practice and outcomes, but they were also aware of the need to use the latest statistical analysis and data management methods:

> *Miss Ruth Doran . . . reviewed the information on the questionnaires that have been filled out by members of the College and [was] able to get some expert statistical advice on how data of this kind might be accumulated in the future. A discussion brought out the following points: It seems advisable to have a system whereby information is currently available. It is possible to set up a coding system in mimeograph form that could be transferred to IBM cards at a later date. A new form for gathering information for statistical purposes is needed.*[106(p13)]

The importance of ongoing collection and analysis of data on the outcomes of midwifery care were documented by nurse-midwifery educators at the first nurse-midwifery education workshop. A summary of this meeting noted that educators were preparing nurse-midwives to

"Participate in the systematic gathering and analysis of data for the purpose of evaluating services which affect the health of mothers and babies, and in implementing the findings."[7(p275)]

During the 1970s and 1980s, the *Journal of Nurse-Midwifery* provided advice and encouragement about the role of research. For example, a 1976 article, "Pragmatics of Research," included practical guidance about research topic-generation and prioritization, the role of collaboration in research, and basic legal issues. Additionally, the author devoted a large portion of the article to advice for practicing midwives who were not actively engaging in research activities:

> *Each nurse-midwife has the responsibility to be an intelligent, critical consumer of research . . . to retrieve research findings with ease, evaluate them as to their soundness, strengths, and weaknesses, and apply them in the clinical setting.* [That responsibility] *also involves providing constructive criticism to researchers by reacting to research findings in discussions and conferences, writing letters to journals and sponsoring organizations, and contacting the individual themselves.*[107(p16)]

In the early 1980s, a series of *Journal of Nurse-Midwifery* editorials explored the topic of nurse-midwifery research from a variety of perspectives. Jacqueline Fawcett, research consultant to the *Journal*, described editorial plans to publish original research articles, with special emphasis on application to clinical practice and replication of previous research. The next year, *Journal* associate editor Evelyn Hart reinforced the imperative for "scientific objective accountability for midwifery practice and education through research." She concluded that:

> *Midwifery has arrived at a point where it must assume responsibility for its own research. A scientific attitude and mode of thinking must be valued by midwives as much as skill and acumen in practice. Midwifery must be conveyed to the public, to physicians, and to other health professionals as a professional service just not only by its art, but also by scientific evidence gleaned from research.*[108(pp37-38)]

During this period, nurse-midwives were systematically compiling and summarizing the outcomes of nurse-midwifery care and using those data to change policy at the local, state, and national levels.[109] In addition to influencing the nurse-midwifery practice and regulation, these data were used to persuade healthcare payers to reimburse nurse-midwives for their services.

By 1988, the volume and complexity of midwifery's research endeavors had grown sufficiently that ACNM leaders and members recognized that the Research and Statistics Committee should move to the Division level. Betty Bear, ACNM president at that time, endorsed the change, and other nurse-midwifery leaders, such as Jeanne DeJoseph, Joyce Roberts, and Claire Andrews, contributed to the successful creation of the Division of Research. Lisa Paine served as the first chairperson.[110]

During the late 1980s and 1990s, nurse-midwives benefited from ever-increasing emphasis on research through participation in grant-funded studies; development of data sets; publication

of research-focused articles in the *Journal of Nurse-Midwifery*; and presentation of ACNM annual meeting poster sessions, research forums, and educational sessions and workshops.[110] Indeed, *Journal* readers were challenged to expand their ideas and their practice through articles such as Joyce Fitzpatrick's "The Clinical Nurse-Midwife as Scientist." In that article, Fitzpatrick asked readers: "Why science? Why research? What does knowledge development have to do with the clinical nurse-midwife? Science thrives by asking impertinent questions and getting revolutionary answers. It is time for some revolutionary answers about health and health care delivery."[111(p37)]

Midwifery's Rich Heritage of Theory Development and Clinical Research

Throughout the history of their profession, nurse-midwives have shaped that profession through theory development and exploration of the meaning of the midwifery model of care.[112] The efforts of midwifery theorists have collectively defined the midwifery model of care, including Ernestine Wiedenbach's work on family-centered maternity care [86]; Ela-Joy Lehrman's work on family-centered care, health education, and advocacy for non-intervention[113]; Joyce Thompson's writings about human dignity and self-determination[114]; Holly Powell Kennedy's work on compassion and careful non-intervention[115]; and Jo Anne P. Davis's work defining normalcy.[116]

In addition to theory development, midwives have a rich history of researching many different aspects of care; much of this research is presented in various chapters of this text. Selected examples include the prenatal care model known as CenteringPregnancy[117]; components of prenatal care provided by nurse-midwives compared to physicians[118]; noninvasive methods of assessing uterine size, gestational age, and fetal presentation and position[119]; management of the perineum at birth and the value of delayed cord-clamping[120,121]; position, breathing, and timing of pushing in the second stage of labor[122]; and home birth and birth center outcomes.[90-92,123] Knowledge about perinatal mood disorders and newborn care has also been furthered by midwifery researchers.[124,125]

Summary

Beginning with early nurse-midwives documenting the outcomes of their care in the Frontier Nursing Service and the Maternity Center Association, midwives have diligently contributed to the body of knowledge about midwifery care and women's health. As the result of ACNM's leadership and the work of theorists, researchers, and clinicians, midwifery has a rich research heritage.

Nurse-Midwifery Education

Midwifery could not exist without midwifery education. The history of this education has some notable features: the interconnectedness of educational programs across time and geography; the little-told stories of programs designed specifically to educate black nurse-midwives; the ebb and flow of programs opening and closing; the long-standing commitment to the hallmarks of midwifery care; and the use of educational innovations to enhance learning and skill development and to make midwifery education more widely available, particularly to rural and underserved populations.

Educational Program Interconnectedness: 1930s to the Present

The first nurse-midwifery education program in the United States was New York City's Manhattan Midwifery School, which operated from 1925 to 1931. Little is known about this program, but subsequent nurse-midwifery education programs in the United States can be connected through a clear "genealogy" of programs. The second and third programs to open in the United States constitute what Helen Varney Burst and Joyce Thompson term "first-generation" programs.[126] In 1932, the School of the Association for the Promotion and Standardization of Midwifery opened. Commonly known as the Lobenstine Midwifery School, it became the Maternity Center Association School of Nurse-Midwifery in 1934 (**Figure 1-6** and **Figure 1-7**). The next program, which opened in 1939, was the Frontier Graduate School of Midwifery of the Frontier Nursing Service (FNS) in Hyden, Kentucky, which later became the Frontier School of Midwifery and Women's Health and more recently was renamed Frontier Nursing University.

Figure 1-6 In the late 1930s, a student nurse-midwife at Maternity Center Association's Lobenstine School of Midwifery is taught how to perform blood pressure measurement by Rose McNaught.

All subsequent nurse-midwifery education programs are closely linked, with second-generation programs being started by graduates of the MCA and FNS programs. Likewise, third-generation programs were started by graduates of second-generation programs, and so on. Even the newest programs are third- or fourth-generation programs, demonstrating the tight interconnectedness of nurse-midwifery educational programs (**Table 1-1**). In 2003, Helen Varney Burst and Joyce Thompson eloquently described the significance of these connections to nurse-midwives:

Table 1-1 **Timeline and "Generation" of Midwifery Educational Programs**

Educational Program, Affiliation, and Location	Burst/Thompson "Generation" of Program	Year Opened	Year Closed
Manhattan Midwifery School, affiliated with the Manhattan Maternity and Dispensary; program under jurisdiction of the hospital's School of Nursing, New York, NY	n/a	1925	1931
School of the Association for the Promotion and Standardization of Midwifery (commonly known as the Lobenstine Midwifery School); became the Maternity Center Association School of Nurse-Midwifery in 1934. Affiliated with Downstate Medical Center, State University of New York, and Kings County Hospital, Brooklyn, New York, in 1958; also includes an early affiliation of Maternity Center Association (MCA) and Kings County Hospital with Johns Hopkins University during 1958–1960, New York, NY	First	1932	Open today (as State University of New York [SUNY] Downstate)
Frontier Graduate School of Midwifery of the Frontier Nursing Service, Hyden, KY	First	1939	Open today (as Community-based Nurse-Midwifery Education Program [CNEP]/ Frontier Nursing University)
Tuskegee School of Nurse-Midwifery; a joint project of the Macon County Health Department, the Children's Bureau, the Julius Rosenwald Fund, Tuskegee University (although not officially part of Tuskegee University), and the Alabama State Department of Health, AL	Second	1941	1946
Flint-Goodridge School of Nurse-Midwifery; in connection with Flint-Goodridge Hospital and Dillard University; first nurse-midwifery program to be affiliated with a university, New Orleans, LA	Second	1942	1943
Catholic Maternity Institute School of Nurse-Midwifery, Santa Fe, NM	Second	1945	1968
Catholic University of America; affiliated with Catholic Maternity Institute; first nurse-midwifery education program to be part of a master's degree program, Washington, DC	Second	1947	1969

[a] Focused programs for internationally educated midwives to prepare for practice in the United States.

How many of us can actually say we touched . . . or were touched by . . . our founding foremothers? The answer is . . . every single one of us! . . . Every nurse-

midwife in the country can trace their historical roots across four generations of nurse-midwifery education programs . . . whose roots reach back through their program director one, two, or three generations to either Hattie Hemschemeyer at Maternity Center Association (MCA) or Mary Breckinridge at the Frontier Graduate School of Midwifery of the Frontier Nursing Service (FNS). . . . This process of reaching to our roots . . . is vital to understanding where we have come from and what important components of philosophy and the midwifery model of care have stood the test of time in caring for women and childbearing families.[126(p464)]

Of particular note when examining the interconnectedness of nurse-midwives through education programs are two second-generation programs whose histories have received little attention. The Tuskegee School of Nurse-Midwifery and the Flint-Goodridge School of Nurse-Midwifery were programs for black nurse-midwives, whose first directors were graduates of the MCA school.

Tuskegee School of Nurse-Midwifery: 1940s

Lucinda Canty's 1994 master's thesis provides important documentation of the Tuskegee School of Nurse-Midwifery.[127] This school opened in September 1941 to educate black public health nurses as midwives, with the goal of decreasing maternal and infant mortality in the black communities of the South.[128] The school was a joint project of the Macon County Health Department, the Children's Bureau, the Julius Rosenwald Fund, Tuskegee University (although not officially part of the university), and the Alabama State Department of Health. Program directors included two Maternity Center Association graduates, Margaret Thomas and F. Carrington Owens, and a 1944 Tuskegee graduate, Claudia Durham.[129] The program closed in 1946 after 5 years of operation, during which 31 black nurse-midwives graduated. Although information is not available for all of the Tuskegee graduates, Canty's thesis describes the contributions of 10 of the graduates to the nurse-midwifery profession and to the black community. At least 10 of the Tuskegee graduates worked in health care, and most of them trained and worked with "granny" midwives (traditional apprentice-trained community-based midwives who were not nurses). At least four Tuskegee graduates continued their education after graduating from the Tuskegee School, and several served as nursing educators.

One Tuskegee School of Nurse-Midwifery graduate, Maude E. Callen (**Figure 1-8** and **Figure 1-9**, received national attention in 1951 when *Life* magazine published a photographic essay, "Nurse Midwife Maude Callen Eases Pain of Birth, Life, and Death."[130] After graduating in 1943, Callen practiced in rural Berkeley County, South Carolina, an area in which she resided and in which residents experienced high rates of maternal and infant morbidity and mortality, as well as high rates of tuberculosis and other infectious diseases. The *Life* feature presented Callen's work through approximately 30 compelling photographs and accompanying text that described her relationships with community members and other healthcare workers, her demanding schedule in service to her patients, and the healthcare and economic struggles faced by the population in that community. The national notoriety Callen

gained from the *Life* feature contributed to donations that enabled the opening of the Maude Callen Clinic in Pineville, South Carolina.[127]

Linda Janet Holmes, in her report of the history of midwives of color in the ACNM, *Into the Light of Day*, noted that the *Life* article served an important purpose in depicting "a Black woman in a health care professional role in a mainstream publication" and as a "tireless holistic healer who functions as midwife, bondswoman, dietician, and counselor in her backwoods and deeply impoverished South Carolina community." However, Holmes also points out that the *Life* article referred to Callen by her first name—"a common practice at the time to denote lesser status for Black women"—in spite of the women and families in her community calling her "Miss Callen."[131](p11)

Flint-Goodridge School of Nurse-Midwifery: 1940s

Another pioneering education program that has been largely overlooked in the historical record is the Flint-Goodridge School of Nurse-Midwifery in New Orleans, Louisiana, which was open from 1942 to 1943. For a number of years, the superintendent of Flint-Goodridge Hospital had been interested in establishing a nurse-midwifery training program as a way to decrease the high rates of maternal and infant mortality in New Orleans' black population by

training nurse-midwives as replacements for traditional granny midwives.[132] Established using funds from the U.S. Children's Bureau and the Rosenwald Fund, the Flint-Goodridge School of Nurse-Midwifery was affiliated with Dillard University and Flint-Goodridge Hospital. Public health nurse and Lobenstine/Maternity Center Association nurse-midwifery graduate Kate Hyder was selected to lead the Flint-Goodridge program. A Jamaican midwife and MCA graduate, Etta Mae Forte, served as an additional faculty member.[132] On June 15, 1943, nine months after the first two students were admitted, the Flint-Goodridge School of Nurse-Midwifery graduated those two students. It closed shortly thereafter, though the historical record does not include a complete account of the reasons for the school's closure. According to Horch's thesis, a 1943 Flint-Goodridge Hospital report cited the "war emergency" as the reason for closure and stated that the closure was intended to be "temporary."[132(p45)]

One graduate of the Flint-Goodridge School of Nurse-Midwifery was Deola Lange Cyrus; the other graduate's name is missing from the historical record. Cyrus described her work and the role of lay midwives in Louisiana in the 1940s in a *Quarterly Bulletin of the Louisiana State Board of Health* article. Given that she was a formally educated nurse-midwife, Cyrus's favorable assessment of granny midwives is a noteworthy description of the important role of midwives in that place and time:

> *In Louisiana the plantation midwife continues to play an important role in rural community life. She is regarded as a counselor on family problems, a healer of all ills, a leader in civic affairs, a soothsayer, and a liaison between Negro families and the "boss-man." Above all else, she is the one person who can be depended on when the expectant mother's time is nigh. Neither freezing weather, hurricanes, high water, nor torrid heat will prevent the granny woman from making her appearance when she gets the word.*[132(p51)]

Patterns of Education Programs Opening and Closing: 1960s to the Present

In the decades following the inception of nurse-midwifery education in the United States, distinct patterns emerged, including rapid increases in the number of educational programs opening during periods when midwifery was encouraged. The late 1960s and early 1970s were a time of increased acceptance of nurse-midwifery and widespread proliferation of educational programs. Many factors converged to create the need to educate more nurse-midwives, including official recognition by organized obstetrics, increased visibility and involvement of the women's movement and feminism, increased recognition of nurse-midwifery by consumers, nurse-midwives' involvement in federally funded projects, an insufficient supply of obstetricians to care for post–World War II baby boomers, and demonstration of the effectiveness of the obstetric interdisciplinary team concept.

The 1990s witnessed another growth spurt in nurse-midwifery education programs, with an unprecedented 26 programs opening; by the end of the twentieth century, 45 ACME-accredited basic nurse-midwifery education programs existed. This growth was in part a result of states' recognition of the quality and cost-effectiveness of midwifery care and funding of local programs.[126] Growth of programs preparing candidates for the certified midwife credential has

been slower, with two schools providing this master's degree in 2017 and six states licensing certified midwives at this time.

Despite periods of growth in numbers of programs, midwifery educators have always faced challenges in maintaining programs, and many programs have closed after only a few years or decades of operations. Programs have closed for numerous reasons, such as funding challenges or relocation of resources within a department and development of a new focus for the educational institution. Nevertheless, some programs are now more than a half-century old (e.g., Columbia, Yale, Utah). An editorial in a 1959 *Bulletin of the American College of Nurse-Midwifery* provides a useful look then and now at the ebb and flow of nurse-midwifery education programs:

> *In the realm of experimentation, there has been no evidence of fear. Wherever a possibility for educational improvement or a broader scope of influence arose, nurse-midwives have made the necessary adjustments and moved in to try out another facet of service.*[133(p38)]

Foundational Concepts and Innovations in Midwifery Education

The original list of concepts integral to nurse-midwifery practice included a family-centered approach to health care, effective communication, collaboration with other healthcare providers, client education, continuity of care, community resources, and health promotion. In 1985, the following concepts were added: informed client choice, reproductive bioethical considerations, and birth as a normal physiologic process. Facilitation of healthy family relationships and respect for cultural variations were added in 1992. In 1997, these foundational concepts were renamed "Hallmarks of Midwifery," and some additional concepts were included: menses and menopause as normal processes, the therapeutic value of human presence, and care of underserved populations. Educational programs articulate how these hallmarks are threaded through their curricula as part of their accreditation evaluations.[134]

Nurse-midwifery educators have been early adopters of educational innovations in many forms, including modular programs and distance education. Nurse-midwifery faculty at the University of Mississippi Medical Center developed a mastery learning modular curriculum in 1972. Although the modular approach was not a new concept, few programs used the approach to structure the entire curriculum in a student-centered and flexible way. The modular approach has been so durable that the International Confederation of Midwives still promotes its use in midwifery curriculum development.

Distance education has provided another opportunity for midwifery educators to use innovative approaches to meet the needs of midwifery students and, by extension, women and families. This idea was first implemented for nurse-midwifery education in the 1970s, when pilot programs such as Educational Program Associated in California laid the groundwork on which later programs were built. Distance nurse-midwifery education took a quantum leap forward when combined with web-based technologies in the 1990s.[135] A major contributor to the progress of innovative distance learning was the Community-Based Nurse-Midwifery Education Program (CNEP), begun in 1989 and affiliated with the Frontier Nursing Service.[136]

Summary

Since opening the Lobenstine School, nurse-midwives educated in the United Stated have been connected through a lineage of educational programs, including several programs for black nurse-midwives, whose stories are largely absent from the historical record. All nurse-midwifery educational programs have navigated difficult situations to remain viable, and many programs were unable to remain open, resulting in a pattern of educational programs opening and closing. Throughout, midwifery educators have remained committed to disseminating foundational concepts and introducing innovations.

Conclusion

Just as a clinician can provide optimal care for an individual and family by understanding that person's history, so midwives must understand the profession's history. By exploring these themes and topics, today's midwives can enhance their understanding of the profession's roots and the opportunities and challenges midwives have faced for nearly a century. Armed with that knowledge, midwives can optimally guide the profession through the next century and beyond.

CHAPTER

2

Professional Midwifery Today

DEANNE R. WILLIAMS

The editors acknowledge Susanna R. Cohen and Celeste R. Thomas, who were authors of this chapter in the previous edition.

Introduction

Midwifery today is a healthcare profession whose members provide care for women throughout the lifespan, with an emphasis on promoting and maintaining health. Modern midwifery is recognized locally as well as globally, with standards for education and practice that make it a profession rather than an occupation or vocation. Safe midwifery practice requires skills, knowledge, and judgment in the provision of health care for women and newborns—but being a safe, legal, independent, interdependent, and successful midwife requires much more than clinical competence. This chapter presents an overview of the profession of midwifery in the United States. Many midwives from the United States work internationally to help train midwives and support women in low-resource nations. A guide to becoming an international consultant is included in **Appendix 2A**.

The Profession of Midwifery

To protect their profession from those who suggest that midwives are undereducated, outdated, or unprofessional, it is important for midwives to be able to answer a critical question: What does it take to be a professional?

According to Ament, "[I]n the United States, the overall objective of protecting the public welfare... is accomplished through three interdependent mechanisms: 1) a prescribed, accredited course of study; 2) national certification; and 3) governmental, usually state or other jurisdiction, licensure."[1] In addition, healthcare professionals are expected to codify their body of knowledge in peer-reviewed journals and textbooks. Midwifery leaders and healthcare policy makers are justified in citing the American College of Nurse-Midwives (ACNM) documents that set standards for education and practice as evidence that midwifery, as practiced by certified nurse-midwives (CNMs) and certified midwives (CMs), is a profession and that these professionals should be licensed in all states and territories.

There is a difference between being a member of a profession and being a "professional." As Kennedy stated, the "midwife's professionalism is a key factor in empowering women during the childbearing process."[2] Kennedy identified three dimensions of midwifery professionalism:

- The *dimension of therapeutics*, which illustrates how and why the midwife chooses and uses specific therapies when providing care
- The *dimension of caring*, which reflects how the midwife demonstrates that she or he cares for, and about, the woman
- The *dimension of the profession*, which examines how midwifery might be enhanced and accepted by "exemplary" practice

Kennedy divided the *dimension of therapeutics* into two qualities that must be held in balance: supporting the normalcy of birth, while simultaneously maintaining vigilance and attention to detail, intervening only when necessary. Kennedy's approach to support the normalcy of birth is often described as the "art of doing 'nothing,'"—that is, appearing calm on the outside while inwardly being actively engaged in data collection and critical thinking.[2]

The *dimension of caring* is demonstrated by "1) respecting the uniqueness of the woman and family; and 2) creation of a setting that is respectful and reflects the woman's needs."[2] Midwives explore and honor each individual woman's personal history and cultural context. These clinicians work in partnership with women for the goal of providing emotional support and strengthening self-confidence of women. Although it is controversial to say that others can empower an individual, such support can increase the self-confidence of a woman and facilitates her own empowerment.

Qualities identified by Kennedy as linked to the *dimension of caring* include "an unwavering integrity and honesty, compassion and understanding, the ability to communicate effectively, and flexibility."[2] Midwives are emotion-workers. For example, exemplary midwives are experts at creating physically and emotionally safe clinical settings; midwives who care for women in labor create a peaceful environment that is conducive to a healthy birth

process, maternal satisfaction, and mother–child bonding in the immediate postpartum period; and midwives caring for women who are seeking a method of contraception use the time to develop a trusting relationship and an environment in which women feel safe enough to disclose honest responses to questions about intimate-partner violence.

The *dimension of the profession* focuses on "the delineation, promotion, and sustenance of midwifery as a professional role."[2] Midwives demonstrate this dimension through evidence-based practice, quality and peer review, continuing education, commitment to and passion for the profession, and nurturing and caring for themselves. The exemplary midwife's focus is not just on the individual woman or birth; in addition, the midwife is driven to foster the profession and advocate for improving women's health care locally and globally.

Professional midwifery in the United States, as represented by certified nurse-midwives, certified midwives, and certified professional midwives, is a dynamic profession. The transition from a focus on individual practice to a focus on the status of a profession within a civil society resembles the evolution of midwifery around the world. In the United States, the scope of midwifery practice has expanded beyond the childbearing years, the core knowledge needed to provide safe care has grown at a rapid pace, and the need to promote interdisciplinary teamwork is well understood. Simultaneously, the civil society has expanded its expectations for all healthcare professionals, and midwives have responded by adopting new standards for education and practice.

Types of Midwives

While an increasing number of individuals are familiar with and use the services of midwives, most midwives have been asked the following questions about their profession: What is the difference between a certified nurse-midwife (CNM), a certified midwife (CM), and a certified professional midwife (CPM)? What is a lay midwife? A direct-entry midwife? An indigenous midwife? While the answers to these questions are evolving, and they can be both confusing and controversial, an exploration of the similarities and differences between midwives is important to the profession and is summarized in **Table 2-1**.[3] The regulatory requirements and scope of practice described here were current as of the time of this text's publication. Laws pertaining to midwifery practice will, like many other statutes, evolve as the political process reflects broader social and cultural changes.

Table 2-1 **Types of Midwives in the United States**

National Midwifery Credentials in the United States	Certified Nurse-Midwife	Certified Midwife	Certified Professional Midwife
Education			
Minimum degree required for certification	Graduate Degree		Certification does not require an academic degree, but is based on demonstrated competency in specified areas of knowledge and skills.
Minimum education requirements for the admission to midwifery education program	Bachelor's Degree or higher from an accredited college or university AND Earn RN license prior to or within midwifery education program	Bachelor's Degree or higher from an accredited college or university AND Successful completion of required science and health courses and related health skills training prior to or within midwifery education program	High school diploma or equivalent Prerequisites for accredited programs vary, but typically include specific courses such as statistics, microbiology, anatomy, and physiology, and experience such as childbirth education and doula certification. There are no specified requirements for entry to the North American Registry of Midwives' (NARM) Portfolio Evaluation Process (PEP) pathway, an apprenticeship process that includes verification of knowledge and skills by qualified preceptors.
Clinical experience requirements	Attainment of knowledge, skills, and professional behaviors as identified by the American College of Nurse-Midwives (ACNM) Core Competencies for Basic Midwifery Education Clinical education must occur under the supervision of an American Midwifery Certification Board (AMCB)-certified CNM/CM or other qualified preceptor who holds a graduate degree, has preparation for clinical teaching, and has clinical expertise and didactic knowledge commensurate with the content taught; > 50% of clinical education must be under CNM/CM supervision		Attainment of knowledge and skills, identified in the periodic job analysis conducted by NARM. NARM requires that the clinical component of the educational process must be at least two years in duration and include a minimum of 55 births in three distinct categories. Clinical education must occur under the supervision of a midwife who must be nationally certified, legally recognized and who has practiced for at least three years and attended 50 out-of-hospital births post-certification. CPMs certified via the PEP may earn a Midwifery Bridge Certificate (MBC) to demonstrate they meet the International Confederation of Midwives (ICM) standards for minimum education.
Education Program Accrediting Organization			
	The Accreditation Commission for Midwifery Education (ACME) is authorized by the U.S. Department of Education to accredit midwifery education programs and institutions. Midwifery education programs must be located within or affiliated with a regionally accredited institution		The Midwifery Education Accreditation Council (MEAC) is authorized by the U.S. Department of Education to accredit midwifery education programs and institutions. The scope of recognition includes certificate and degree granting institutions, programs within accredited institutions, and distance education programs.

Scope of Practice			
Range of care provided	Midwifery as practiced by CNMs and CMs encompasses a full range of primary health care services for women from adolescence beyond menopause. These services include the independent provision of pre-conception care, care during pregnancy, childbirth and the postpartum period, care of the normal newborn during the first 28 days of life, primary care, gynecologic and family planning services and treatment of male partners for sexually transmitted infections CNMs and CMs provide initial and ongoing comprehensive assessment, diagnosis and treatment. They conduct physical examinations; prescribe medications including controlled substances and contraceptive methods; admit, manage and discharge patients; order and interpret laboratory and diagnostic tests and order the use of medical devices Midwifery care also includes health promotion, disease prevention, and individualized wellness education and counseling		Midwifery as practiced by CPMs offer expert care, education, counseling and support to women and their families throughout the caregiving partnership, including pregnancy, birth and the postpartum period. CPMs provide on-going care throughout pregnancy and continuous, hands-on care during labor, birth and the immediate postpartum period, as well as maternal and well-baby care through the 6–8 week postpartum period. CPMs provide initial and ongoing comprehensive assessment, diagnosis and treatment. CPMs are trained to recognize abnormal or dangerous conditions requiring consultation with and/or referral to other health care professionals. they conduct physical examinations, administer medications and use devices as allowed by state law, order and interpret laboratory and diagnostic tests.
Practice settings	All settings - hospitals, homes, birth centers, and offices. The majority of CNMs and CMs attend births in hospitals		Homes, birth centers, and offices. The majority of CPMs attend births in homes and birth centers
Prescriptive authority	All U.S. jurisdictions	New York, Rhode Island, Maine	CPMs do not maintain prescriptive authority; however, they may obtain and administer certain medications in select states
Third party reimbursement	Most private insurance, Medicaid coverage mandated in all states; Medicare, TRICARE	Most private insurance, Medicaid coverage in New York, New Jersey, Rhode Island	Private insurance mandated in 6 states; coverage varies in other states; 13 states include CPMs in state Medicaid plans.
Certification			
Certifying organization	American Midwifery Certification Board (AMCB)		North American Registry of Midwives (NARM)
	AMCB and NARM are accredited by the National Commission for Certifying Agencies		
Requirements prior to taking national certification examination	Graduation from a midwifery education program accredited by the Accreditation Commission for Midwifery Education (ACME); AND Verification by program director of completion of education program		Completion of NARM's Portfolio Evaluation Process (PEP) OR Graduation from a midwifery education program accredited by the Midwifery Education Accreditation Council (MEAC) OR AMCB-Certified CNM/CM with at least ten community based birth experiences

Certification			
	AND Verification of master's degree or higher **CNMs must also submit evidence of an active RN license at time of initial certification*		OR Completion of an equivalent state licensure program include a new sentence below: All applicants must also submit evidence of current adult CPR and neonatal resuscitation certification or course completion.
Recertification requirement	Every 5 years		Every 3 years
Licensure			
Legal status	Licensed in 50 states plus the District of Columbia and US territories as midwives, nurse-midwives, advanced practice registered nurses, or nurse practitioners	Licensed in Delaware, Maine, New Jersey, New York, and Rhode Island	Licensed or otherwise regulated in 31 states (4 states regulate by registration, certificate or voluntary licensure)
Licensure agency	Boards of Midwifery, Medicine, Nursing, Nurse-Midwifery, or Departments of Health	Boards of Midwifery, Medicine, Complementary Health Care Providers or Departments of Health	Boards of Midwifery, Medicine, Nursing, Complementary Health Care Providers or Departments of Health or Departments of Professional Licensure
Professional Association			
	American College of Nurse-Midwives (ACNM)		National Association of Certified Professional Midwives (NACPM)
Other Midwifery Organizations			
	Midwives Alliance of North America (MANA) International Center for Traditional Childbearing (ICTC)		

Note: This table does not address individuals who are not certified and who may practice midwifery with or without legal recognition.

Reproduced with permission from American College of Nurse-Midwives. Comparison of certified nurse-midwives, certified midwives, certified professional midwives clarifying the distinctions among professional midwifery credentials in the U.S. Available at: www.midwife.org/Updated-CNM-CM-CPM-Comparison-Chart-October-2017. Accessed November 15, 2017.[3]

Terms such as "lay midwife" and "direct-entry midwife" lack a common definition. For some, the term "lay midwife" describes an individual who has no formal education as a midwife, while others use this term to refer to a midwife who is not recognized by a government entity. The term "direct-entry midwife" typically refers to a midwife who has entered the profession without first becoming a nurse. In some states, direct-entry and licensed midwife are categories of licensure that co-mingle a variety of midwives and are separate from the licensure of CNMs.

The terms "traditional midwife," "community midwife," and "indigenous midwife" acknowledge the women or men who follow traditional customs as they attend births in their community. These midwives typically work in areas where they have limited access to the

formal education and well-staffed hospitals found in larger cities. Traditional midwives often are or have learned from elders who are influential and trusted because they provide care in concert with local belief systems. Examples include aboriginal midwives from Canada, *comodronas* from Guatemala, and *parteras f*rom Mexico. Traditional apprentice-trained midwives have a large role in provision of maternity care in low-resource nations. Readers interested in learning more about the history and current role of these midwives can refer to the Resources section at the end of this chapter.

As the population of the United States becomes more diverse, one can expect to find traditional midwives serving their newly established communities. It is a mistake to assume that women who receive care from these midwives have poor outcomes or to inject new providers into a community without building a collaborative relationship with traditional midwives. Because hospital-based birthing and fear of complicated birth have become the cultural norm in the United States, criticism of women who chose alternative settings or providers sometimes seems to be common. Nevertheless, women who fear iatrogenic complications, unnecessary cesarean sections, and loss of precious time with their families before and after birth can find evidence to support their concerns about the hospital-based model. Midwives have the opportunity to promote a healthcare system where normal healthy women with uncomplicated pregnancies receive care from well-educated midwives and have access to out-of-hospital childbirth. If complications develop, the healthcare system should be designed so these women have immediate, nonpunitive access to a setting where appropriate care is available. Midwives also have the opportunity to decrease the rate of unnecessary interventions and increase the level of satisfaction for women who give birth in the hospital setting.

Prior to the 1990s, many midwives in the United States who were not CNMs resisted becoming nurses in order to be eligible for midwifery education programs and were opposed to adopting national standards for education and certification. This resistance partly stemmed from concerns that the next steps would be formal education requirements that did not recognize apprenticeship education, followed by required state licensure. Being a “lay midwife” and attending home births is seen by some midwives as the ultimate in independent practice and a source of pride.

The CPM credential, which was first issued in 1994, was originally developed to provide competency-based certification for midwives who were primarily apprentice trained in out-of-hospital birth. The natural consequences of creating the CPM certification examination were the obligation to ensure that those who take the examination meet common standards for education and practice and the creation of a structure within which to discipline those who do not perform in a manner consistent with the standards. Standards for education, certification, and practice for CPMs have been developed, and CPMs continue to seek to expand licensure in states that do not currently have CPM licensure statutes.[4]

At approximately the same time as the development of the CPM credential, in 1991, the board of directors of the American College of Nurse-Midwives (ACNM) endorsed the development of an alternative educational path to midwifery that did not require a nursing degree and that would lead to the CM credential. Over the next 7 years, the requirements to accredit education programs and certify graduates who were not registered nurses were

designed and tested to ensure that, after graduation and certification, one could not distinguish between the knowledge and skills of a CNM and a CM. The first CM credential, which required passing the same certification examination that is offered to nurse-midwives, was issued in 1998.

Although significant variations between CPMs, CNMs, and CMs still exist (**Table 2-1**), the collaborations between the three membership organizations for midwives—the ACNM, the Midwives Alliance of North America (MANA), and the National Association of Certified Professional Midwives (NACPM)—focus more on common values and goals than on differences.[5]

It is increasingly clear that in the United States, where the consumer may find it difficult to distinguish between the various types of midwives who have different credentials, each individual who uses the title “midwife” assumes responsibility for the image of the entire profession. Since the publication of the International Confederation of Midwives (ICM) standards on education and regulation, the professional organizations representing midwives in the United States have engaged in regular discussions about how to meet and support the ICM standards and increase access to high-quality midwifery care in a variety of settings. These discussions have sought to clarify the differences between CNMs, CMs and CPMs. Over time, the differences may decrease.

It is also wise to remember that very few of the midwifery profession’s labor-intensive accomplishments would have moved from internal ideals to cultural norms without consumer support. From the Maternity Center Association (now known as the Childbirth Connection and a program in the National Partnership for Women and Families) to Citizens for Midwifery, consumers have provided inspiration, influence, and financial resources to promote and protect access to midwifery care.[6,7] The list of individuals who created a public demand and stood beside midwifery during some difficult times is long and diverse.

Core Competencies

Core competencies delineate expected fundamental knowledge, skills, and behaviors. These statements serve as the reference point for standardization of the curricula for otherwise diverse education programs and the criteria for accrediting education programs, including those that are not within colleges or schools of nursing. Core competencies inform regulatory agencies, consumers, and employers of what, at a minimum, can be expected from those who graduate from an accredited program.

Using core competencies as a measurement of a student's success enables education programs to recognize that many individuals enter midwifery programs with preexisting skills. It also enables students to focus their studies on new areas, rather than repeating previously learned information. In addition, clear, meaningful competencies reassure the public as well as the midwifery community that all accredited programs graduate well-prepared individuals.

Hallmarks of Midwifery

The *Core Competencies* include six overarching competencies, each of which delineate the skills and knowledge that can be expected of new graduates of ACME accredited midwifery education programs. While each of the competencies describes critical skills and knowledge necessary for midwifery practice, it is the first competency—the *Hallmarks of Midwifery*—that provides the foundation upon which midwifery practice is built. These hallmarks describe the characteristics of midwifery care that are unique to the profession; characteristics that reflect the philosophy of ACNM and highlight components of care that are valued by midwives. A link to the full *Core Competencies* can be found in the Resources section of this chapter, and the *Hallmarks of Midwifery* are presented in **Table 2-2**.[8]

Table 2-2	**Hallmarks of Midwifery**
The art and science of midwifery are characterized by the following hallmarks:	
Recognition of menarche, pregnancy, birth, and menopause as normal physiologic and developmental processes	
Advocacy of non-intervention in normal processes in the absence of complications	
Incorporation of scientific evidence into clinical practice	
Promotion of woman- and family-centered care	
Empowerment of women as partners in health care	
Facilitation of healthy family and interpersonal relationships	
Promotion of continuity of care	
Health promotion, disease prevention, and health education	
Promotion of a public health care perspective	
Care to vulnerable populations	
Advocacy for informed choice, shared decision making, and the right to self-determination	
Integration of cultural humility	
Incorporation of evidence-based complementary and alternative therapies in education and practice	
Skillful communication, guidance, and counseling	
Therapeutic value of human presence	
Collaboration with other members of the interprofessional healthcare team	

Reproduced with permission from American College of Nurse-Midwives. *Core Competencies for Basic Midwifery Practice*. Silver Spring, MD: American College of Nurse-Midwives; 2012.[8]

Accreditation

Earning a college degree is a significant measure of success in the United States. A degree represents knowledge obtained in an institution that adheres to national standards that are established to ensure preparation of students who are well educated, by qualified faculty, in their chosen field. Students, employers, and consumers want to know that a degree reflects mastery of a prescribed set of knowledge and skills.

To increase the value of formal education and to protect students from fraud, the federal government and professional education organizations have established standards for institutions of higher education that address the learning environment, content of the curriculum, and qualifications of faculty. In the case of midwifery, the Accreditation Commission for Midwifery Education (ACME) has been recognized by the U.S. Department of Education as a programmatic accrediting agency since 1982 for nurse-midwifery education programs and since 1994 for direct-entry midwifery programs. Maintaining midwifery accreditation standards that are separate from those required for nursing education has allowed the CNM/CM profession to self-regulate, maintain a strong public voice for improving access to midwifery care, and influence public policy that affects the health of women and families.

Certification

While accreditation recognizes educational programs, certification recognizes the individual professional. For CNMs and CMs, certification—that is, passing an examination that measures mastery of fundamental knowledge needed for safe practice and obtained through a recognized program of study—is required to obtain a state license to practice, to obtain hospital staff privileges, and to qualify for reimbursement from public and private health insurance plans. The criteria for taking the examination, the content of the examination, and the requirements for maintaining certification are developed under the auspices of organizations that do not serve as advocates for the profession. While members of the profession can serve as expert advisors, certification organizations work to protect the recipients of care and follow the standards established by the National Commission for Certifying Agencies. CNMs have been certified by examination since 1971, CPMs since 1994, and CMs since 1998.

Licensure and Regulation

The assumption of responsibility for the life and health of another individual—or individuals, in the case of the maternal–fetal dyad—comprises a legal and social contract with multiple contingency clauses. State legislators have responsibility for protecting citizens from unsafe healthcare practitioners and do so by creating state laws that govern practice. State agencies are charged with adopting rules and regulations that further clarify the law. A typical state midwifery practice act will establish (1) qualifications for initial and renewed licensure, (2) scope of practice, (3) relationship with physicians, (4) prescriptive authority with special requirements related to prescribing controlled substances, and (5) definitions of unlawful or unprofessional conduct. Because the laws governing licensure are forged through the legislative process, they are subject to the influence of multiple stakeholders. Additionally, the process of getting a bill passed can be unpredictable. As a result, there is variation in midwifery scopes of practice and requirements for licensure or authorization to practice from state to state.

Many state practice acts are not entirely consistent with the standards of practice endorsed by professional midwifery organizations and taught in accredited midwifery education programs. Despite this discrepancy, the recognized midwife is expected to follow the rules and regulations for whatever method of authorization he or she is granted by the state.

The practice of midwifery is also subject to state and federal laws governing the practice of medicine, Medicare and Medicaid payment, pharmacy, controlled substances, hospital accreditation, and licensing of freestanding birth centers. Going beyond the expectations of regulators, professionals also assume responsibility for setting and meeting their own standards of performance.

Code of Ethics

Ethics is defined as a guiding set of principles that inform actions.[9] Midwives must be well versed in the ethics involved in all healthcare interactions.[10,11] The subject of professional ethics in health care is complex, however, and the brief introduction presented here is not a comprehensive review of this important topic. Additional resources that address health literacy, health numeracy, values clarification, options counseling, the interface between legal and ethical issues, and ways to communicate risk are listed at the end of this chapter. The *ACNM Code of Ethics with Explanatory Statements* provides an in-depth review of common ethical dilemmas faced by midwives and provides guidance for resolving these dilemmas.[12]

An ethical framework for practice, beginning with the concept of accountability, is critical to the continuation of midwifery as an independent and respected profession.[10,11] As defined in the ACNM's *Code of Ethics*, CNMs and CMs have three ethical mandates: to individual recipients of care; for the public good; and to the profession of midwifery. Ethical guidelines encourage self-regulation, foster professional identity, protect midwives and clients, and serve as a measure of professional maturity.[9]

The *ACNM Code of Ethics* was first published in 1990, and the ICM ethical code was introduced in 1993. These documents, as well as MANA's *Statement of Values*, provide guidance for the ethical behavior of midwives in various roles, including caring for women and their families, education, research, public policy, business management, and financial organization of health services.[13,14]

Bioethical Principles

Bioethics is the ethics of working with or caring for human beings. Four broad ethical principles define modern bioethics: respect for autonomy, nonmaleficence (do no harm), beneficence (do good), and justice (**Table 2-3**).[15,16]

Table 2-3 Bioethical Principles

Bioethical Principle	Definition	Midwifery Application
Autonomy	Self-determination	The midwife respects the right of the woman to make decisions regarding her care.
Beneficence	Do good	The midwife acts in a way that promotes the woman's best interests and well-being.
Nonmaleficence	Do no harm	The midwife avoids any actions that cause harm to the woman or her infant.
Justice	Fairness	The midwife accords the woman her due rights and treats all women equally.

Respecting an individual's privacy, ensuring confidentiality, and encouraging shared

decision making are all extensions of these bioethical principles. Research has shown that when healthcare providers do not respect these rights, their behavior may be seen as a form of abuse and could lead to psychological trauma for the woman.[16] Healthcare professionals can also experience ethical dilemmas when the application of one ethical principle appears to contradict a second principle.

Privacy and Confidentiality

Protection of a woman's privacy is not just ethical; in most cases it is also mandated by the Health Insurance Portability and Accountability Act of 1996 (HIPAA). When working in collaboration with other healthcare providers, only those aspects of health information that are immediately pertinent to the individual's care should be disclosed, and the woman should be personally notified if the midwife desires to contact a consultant about the woman's health.

Family members, partners, or friends are often present during office visits or in a birthing site. It is important to privately confirm that the woman has given permission to share personal health information when others are present. A midwife must also be diligent about not discussing client information in places where third parties might overhear. Sharing protected health information via emails, faxes, digital records, the Internet, and social media can all lead to inadvertent breaches in confidentiality that can lead to serious negative consequences.

Shared Decision Making

The concept of *informed consent*—a term often used in legal circles—evolved through court decisions and government regulations. It was not until the 1950s and 1960s that U.S. courts began to mandate that consent be obtained before surgery. The 1970s saw an explosion of court rulings that provided legal guidance regarding informed consent.[17,18]

The ethical foundation for informed consent is a woman's understanding of the recommended treatment and her free consent to that treatment.[19] The components that must be shared with the woman to obtain her informed consent are six-fold: (1) diagnosis or assessment, (2) purpose of the proposed treatment or procedure, (3) possible risks of the treatment, (4) possible benefits of the treatment, (5) alternative treatments and the risks and benefits of those alternatives, and (6) possible benefits and risks of not receiving the treatment or procedure. The assumption underlying informed consent is that the individual is capable of understanding the content of the discussion so that self-determination may be protected and supported.

The term "informed decision making" encompasses both informed consent (providing required information) and informed refusal, and reflects a higher ethical standard than that required by law. Foster identified three essential components of informed decision making: (1) *knowing* or understanding, (2) *competency*, and (3) *voluntary* permission.[8] The ethical/moral interpretation of informed decision making centers on autonomous choice: Was the woman able to exercise her right to decide what happens to her body?

Shared decision making with the right to informed refusal is a more recent ethical approach and is consistent with the ACNM philosophy and core values. It is defined as "an approach

where clinicians and patients share the best available evidence when faced with the task of making decisions, and where patients are supported to consider options, to achieve informed preferences."[20-22] This approach has gained favor as healthcare providers rely more on evidence-based practice that includes disclosure of areas where evidence is scarce or contradictory.

Facilitating shared decision making is a process that may take several conversations. Women need time to process information and ask questions. Healthcare consumers may need concrete explanations to understand the information well enough to make a decision. In addition, a woman's health literacy, her cognitive ability, or the presence of physical, intellectual, or developmental disabilities must be taken into consideration. Some women may experience personal circumstances that curtail their ability to make a decision voluntarily—for example, pressure from family members, the midwife, or other care providers; environmental factors such as lack of privacy, lack of funding, or restriction of healthcare access; and/or an abusive relationship. The midwife must assess for these factors and take into account the cultural context when determining whether the woman is able to make a decision on her own volition at any given time.[18,23,24]

Ethical Dilemmas

Professional ethics dictates that a conflict between two or more moral obligations in a particular situation be addressed through deliberate ethical analysis and decision making, including weighing and balancing principles, and preferably involving and achieving consensus among all affected parties. For example, one healthcare provider's attempt to "do good," such as performing a cesarean section for a diagnosis of failure to progress, might be interpreted by the recipient of care as "doing harm"—in this case, performing surgery without adequate time waiting for a vaginal birth.

Equally challenging is the fact that midwifery is a field in which the professional attending a birth has two individuals for whom to provide care, the mother and the fetus, whose interests may not be in equipoise. However, a woman's right to autonomy does not change because she is pregnant. The consensus of modern ethics is that the duty owed to the fetus may be different from that owed to the mother, and the duty to both change depending on the gestational age and maternal condition(s).[24]

Examples of ethical scenarios are presented in **Table 2-4** and **Table 2-5**.

Table 2-4	**Ethical Scenario 1**
A woman with a low-risk pregnancy is "miserable" and requests an induction at 37 weeks' gestation. She is adamant that she will go elsewhere for her care if the midwife will not induce her labor. The midwife validates the woman's feelings and explains the risks of elective induction but supports the position that induction at 37 weeks is not recommended.	
The midwife knows that the benefits to the woman and fetus are maximized (*beneficence*) and harm is minimized (*nonmaleficence*) with spontaneous labor. This professional must weigh this information with the principle of *autonomy*, the woman's right to make an informed decision about her body and fetus.	

Table 2-5	Ethical Scenario 2
A woman presents for her first visit of the pregnancy and tells the midwife that she is uninsured and does not have many financial resources. Normally the midwife counsels women about their genetic testing options in pregnancy at the first visit. It becomes clear to the midwife in the course of their conversation that the woman would not be able to afford any of the costly genetic testing and wonders if counseling should be performed. The midwife decides to counsel this woman in the same manner as any other woman. The midwife's decision to counsel this woman regardless of her ability to afford genetic testing illustrates the principle of *justice*.	

Midwives in the United States

There is no single typical midwife. Nevertheless, demographic data have been collected regularly for more than 50 years for CNMs and provide an insight into both some changes in this profession and some factors that remain the status quo.

Demographic Characteristics

Descriptive data regarding members of ACNM have been collected through membership surveys for more than 5 decades. In the 1963 survey, 229 members were mailed the survey questionnaire and 72% responded.[25] The survey revealed a median age of 41 years for respondents, the existence of six educational programs, and a geographic distribution of practices primarily clustered on the East Coast. Several states or jurisdictions had laws prohibiting midwifery practice. Reports from the 2012–2013 surveys found that the average midwife was a bit older at 50 years; there were more than 40 educational programs; and CNMs practiced in all 50 states, with distribution similar to the general distribution of the U.S. population.[26]

Racial Diversity

One thing that has not changed dramatically over the last half-century is the racial diversity of practicing midwives.[27,28] The population of the United States is increasingly diverse, yet racism, when it is institutionalized, often goes unrecognized by those who are white and racial disparities in maternal and early childhood health outcomes have not significantly improved despite a variety of attempts to increase access to and quality of care.[29] While the midwifery profession has a long history of serving women who are at risk for poor pregnancy outcomes, one solution remains a challenge for the profession—the evidence that race-concordant care can reduce racial disparities in health.[30] While there is recent evidence of an increase in the number of new CNMs/CMs who identify as people of color (14.5% in 2013), the ACNM membership remains disproportionally (more than 90%) white.[26]

The November/December 2016 issue of *Journal of Midwifery and Women's Health* (*JMWH*) provided a comprehensive review of the prolonged struggle to identify and embrace tangible actions that will increase diversity in those who choose the profession of midwifery. The content of this issue of *JMWH* leaves no doubt that changes are needed.[31] Recent actions designed to improve the diversification of the midwifery workforce include the work of the ACNM Diversification and Inclusion Taskforce, which published *Shifting the Frame: A Report on Diversity and Inclusion in the American College of Nurse-Midwives*; provision of antiracist training to the ACNM's board of directors and staff; a theme issue of *JMWH* that explored the problem of racial diversity and the publication of a racial equity toolkit; recent appointment of a member of the Midwives of Color committee to the ACNM's board of directors; and addition of diversity and inclusion as one of the five core commitments for the 2015–2020 strategic plan for the organization.[32,33] The work of the Diversification and Inclusion Taskforce is documented on the ACNM website.[33] Articles remind the reader that

members experience discrimination and exclusion and that overcoming ethnocentrism extends beyond race and ethnicity.

Diversity and Inclusion with Regard to Gender and Identity

Gender is another demographic characteristic that has not changed dramatically over the years. Although "midwife" means "with woman," it does not mandate that the midwife must *be* a woman. Traditionally, though, midwives have been women. Even today, fewer than 2% of CNMs are men, according to recent surveys.[26] Men in midwifery often find themselves as the target of bias from both women and other professionals, including other midwives.

The ACNM Diversification and Inclusion Taskforce has stated that "Differences in identity include but are not limited to race, ethnicity, culture, class, gender and gender identity, sex, sexual orientation, religion, physical and intellectual ability, nationality, citizenship, age, learning style, mental health, professional background, midwifery certification, or academic degree. Diversity also refers to diversity of thought and perspective that come with individual identity."[33] Many of these factors have not been the subject of surveys, but it may be assumed that in some ways midwifery reflects diversity within the general population.

Clearly, midwifery is not a monolithic profession. Some midwives are members of the lesbian, gay, bisexual, transgender, queer, and intersex (LGBTQI) community. They may be religious or not; they may attend temples, churches, or synagogues, or not. Midwives also express a diversity of opinions. For example, in the ACNM there can be civil discussions between members of the caucus focused on reproductive justice and abortion rights and members of the caucus that is pro-life. Midwives do not automatically belong to one political party. Personal scope of practice likewise differs among different midwives.

Midwives have strong opinions, and robust discussion often ensues at their meetings. Nevertheless, respect for others and the goal of caring for women and families should always prevail. Inclusion for all remains an important twenty-first century goal.

Scope of Practice

Midwifery also has a long-standing reputation for preserving a childbirth experience that honors the normal process of birth as well as the transformational power of the childbearing experience.[34] An individual's scope of practice is determined by multiple factors, including legal jurisdiction, institutional policy, location of care, collaborative practice agreements, and individual education and experience.[35] In addition, state laws and facility bylaws may contribute to the definition of the clinical or professional relationship between a midwife and consulting or collaborating physician (**Figure 2-1**). Scope of practice is a complex but dynamic framework for one's clinical practice. For example, a midwife's scope of practice has inflexible boundaries in some aspects (e.g., one cannot perform services that are prohibited by law) and flexible boundaries in other aspects (e.g., advanced clinical skills such as first assisting for cesarean births, may be acquired or needed for a particular setting).[35]

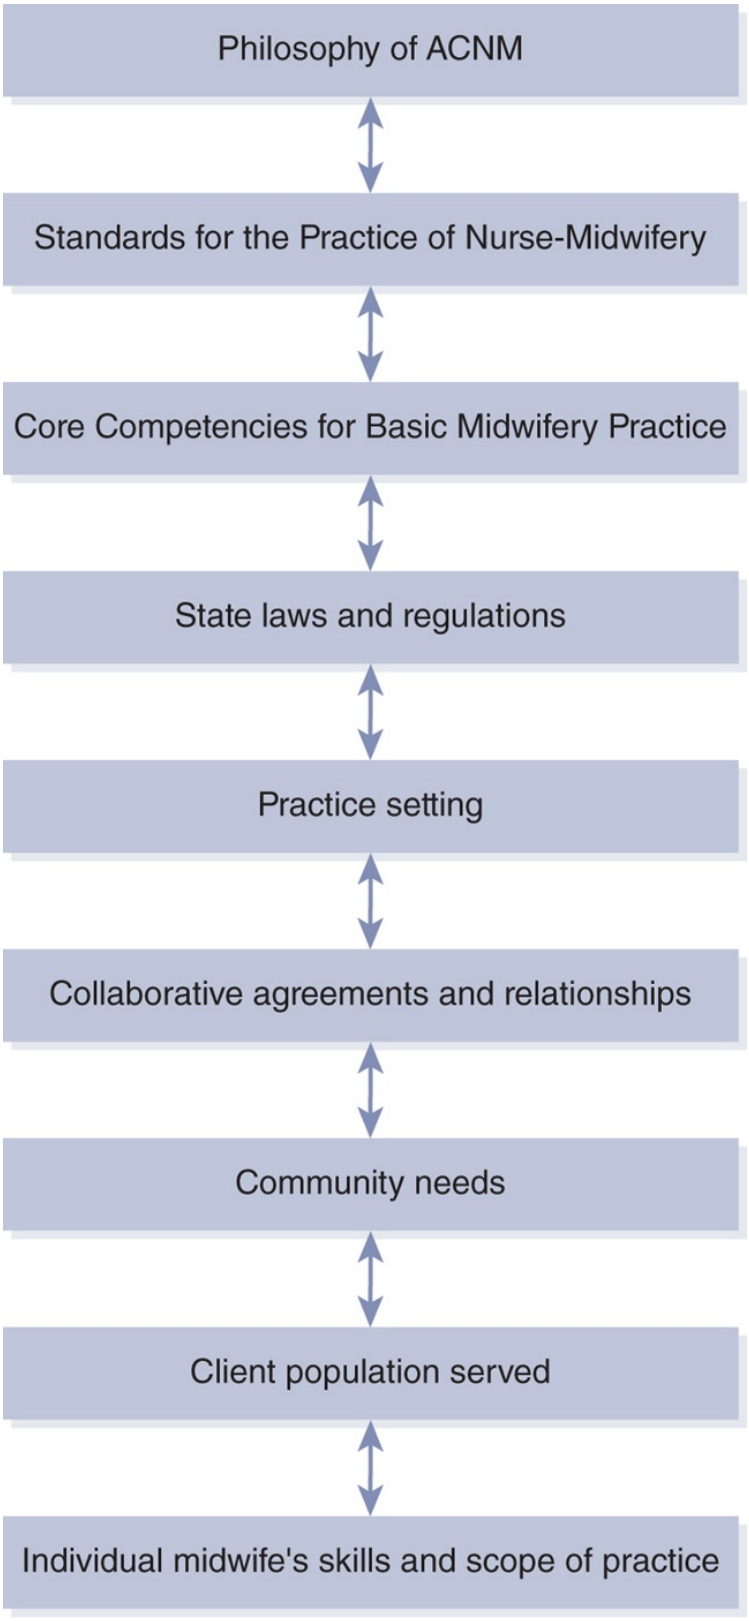

Figure 2-1 Composition of scope of practice.

Modified with permission from Schuiling KD, Slager J. Scope of practice: freedom within limits. *J Midwifery Womens Health*. 2000;45(6):465-471.[35] © 2000, with permission from Wiley.

State laws governing midwifery practice vary. At their best, state laws support independent midwifery practice and collaborative management; at their worst, they require direct physician

supervision of midwives. The rules and regulations governing midwifery practice usually are available on state-sponsored websites. Professional organizations such as ACNM and MANA provide online summaries of all of the states' midwifery laws and work to change laws that do not permit midwives to practice to the full scope of their preparation. A 2015 review by Osborne summarized state regulations regarding prescriptive authority for CNMs and CMs.[36]

Hospital Privileges

Midwives who attend births in a hospital and most birth centers are required to be credentialed and privileged by the healthcare facility prior to caring for women in that setting. Bylaws, as established by the healthcare facility, define the requirements for obtaining privileges, the responsibilities of those who are granted privileges, specific procedures that may be performed by the individual providers, protections offered to those who are privileged, and grounds for removal of privileges. These bylaws may also specify the role and responsibilities of the midwife in relation to the collaborating physician(s) and the responsibilities of the physician in relationship to the midwife. All privileged providers are expected to adhere to institution bylaws, even if the bylaws are more restrictive than the state law.

Practice Patterns

Improving the health of women is a personal, communal, and political responsibility, and midwives work wherever women need them. While many midwives attend births and provide women's health services, they may also work as entrepreneurs, policymakers, and educators. In all of these roles, midwives collaborate with a variety of team members.

In clinical practice, midwives may work for large hospitals or healthcare systems in metropolitan areas, in small private practices in rural communities, and anywhere in between. Midwives may attend births in homes, freestanding birth centers, or hospitals. They may be self-employed in a private business, or they may be employees of physicians or healthcare organizations. They provide care to women from across the socioeconomic spectrum. CNMs and CMs can provide primary health care to women or can limit their practice to women with needs that are age or condition specific, such as family planning, infertility, menopause, incontinence, or pelvic pain. CPMs are typically licensed exclusively to provide maternity care.

Since the 1960s, the majority of CNMs, and now CMs, who attend births have done so in hospitals and freestanding birth centers, whereas the vast majority of CPMs have attended births in homes or freestanding birth centers. Although these trends may continue for a while, the future may present more workplace opportunities for all midwives.

With so many opportunities, the typical midwife searches for a position that is a good match to his or her experience, personality, skill set, and lifestyle. Many midwives become employees of a practice or facility. When considering an employee position, one of the first actions is for the midwife to perform a personal evaluation: Which work and lifestyle factors are important to the individual midwife? Which skills/talents would be important to stress to a prospective employer? What do employers in the area need or want? When evaluating the positives and negatives of any job, it is important to review various aspects of the business that may contribute to success or frustration—for example, availability of and relationship with physicians and other providers (e.g., dieticians, physical therapists), ancillary support (e.g., billing, office flow), reimbursement for professional expenses (e.g., licenses, certification, and continuing education), payment for malpractice premiums, availability of student loan payments, and retirement benefits.

Malpractice Insurance Coverage

Although relatively uncommon, inadequate malpractice coverage can lead to bankruptcy for a midwife. A midwife who is employed by a large healthcare center or university may be covered by the facility's umbrella policy or, alternatively, may be "indemnified" because the company chooses to self-insure so that all employees who are practicing within their job description have what is considered equivalent to malpractice coverage. For most other midwives, two basic kinds of malpractice insurance policies are available: "claims made" and "occurrence."[37,38] Although more difficult to find, the best policy is occurrence, because it covers a midwife as long as the event occurred when the midwife was covered. Claims-made insurance is more common, but covers the midwife only while the policy is in effect or until a

"tail" is purchased. A midwife with a claims-made policy should purchase tail coverage if she or he will no longer be seeing clients under the terms of that policy, but may be able to obtain prior-acts coverage if a new policy is activated.

A midwife needs to know exactly how she or he will be covered for a malpractice claim that might occur during or after employment. Because the statute of limitations for filing a claim for injury related to childbirth may extend for 18 to 20 years, it is critically important that midwives keep copies of their proof-of-insurance forms until they are well past retirement from clinical practice. In addition, when midwives apply for hospital privileges, they are often asked to provide proof of prior malpractice insurance coverage. Members of the American College of Nurse-Midwives have access to a detailed *Professional Liability Resource Packet* and several liability risk reduction statements.[38] These statements identify conditions that pose a higher risk for a professional liability claim and offer risk reduction strategies to enhance health care, prevent claims, or increase the defensibility of a claim. **Table 2-6** summarizes malpractice insurance for midwives.

Table 2-6 Informed Decision Making When Purchasing Malpractice Coverage

Terms	Explanation	What the Midwife Needs to Know
Indemnification	Large healthcare organizations can be self-insured, meaning they indemnify employees who are named in a malpractice lawsuit. Coverage typically does not extend to work settings not owned by the organization.	What are the payout limits of the policy? The midwife is covered only when her or his actions are consistent with the job description. Is the policy an occurrence or claims-made policy? Pros and cons of purchasing a second policy?
Malpractice policy	Purchased from private insurance companies. Individuals can purchase as an individual, and sometimes midwives are covered as an employee of a physician. Need to be clear regarding the circumstances when the policy will end.	Do I need and can I get prior-acts coverage? Do I need to have my own policy or am I named as an employee on a physician policy? Is this an occurrence policy or a claims-made policy? I have an occurrence policy now; can I purchase prior-acts coverage under my new policy? Can I purchase a tail when I no longer need the policy? If yes, how is that priced?
Claims-made coverage	The insured has malpractice coverage only for claims that are made when the policy is in effect.	Can I purchase a tail when I no longer need this policy? If yes, how is that priced?
Occurrence coverage	The insured has malpractice coverage for any claims about care that occurred when the policy was in effect.	If employment ends, coverage for future events ends but coverage is still in place for events that occurred when the policy was in place. Tail coverage should not be needed.
Going bare	The provider decides to not carry malpractice insurance.	While some consider this approach unethical, the rising cost of premiums often brings up this discussion. Two major concerns need to be considered: (1) Your personal or family savings and property may be at risk and (2) if you apply for hospital privileges in the future, a period of clinical practice without malpractice coverage may lead to denial of privileges.
Limits of	Professional liability policies have	Do state law and/or hospital bylaws dictate the minimum

coverage	two sets of limits: a per claim or incident limit and the aggregate limit that the insurer will pay during the policy period (usually one year).Example: $1 million/$3 million	coverage a midwife must carry?

Modified with permission from American College of Nurse-Midwives. ACNM professional liability resource packet. Available at: http://www.midwife.org/index.asp?bid=59&cat=5&button=Search&rec=134. Accessed June 3, 2017.[38]

The Midwife as an Employee

Whether considering one or multiple job opportunities, the midwife should analyze a number of factors that will influence his or her job satisfaction, some of which can be found in **Table 2-7**. This table is designed for a midwife who is interested in joining an existing practice as an employee. The weight of any of the factors will vary based on the individual midwife's desires and needs. The factors are not presented in any specific order, nor is this an exclusive list.

Table 2-7 Factors to Clarify When Considering Joining a Practice

Practice Characteristics	Compensation/Benefits
Location	Salary
Philosophy	Productivity
Clientele (volume, demographics, current outcomes of care)	Requirements/bonuses/overtime
Practice providers (physicians, midwives, nurse practitioners, others, and culture of collaboration)	Payment/nonclinical responsibilities
Support staff (billing, assistants in office, marketing)	Ability to own part of the practice
Clinical hours	Malpractice insurance (type, tail if needed)
Environment (equipment, facilities, financial stability)	Vacation/paid time off
Birth facility	Maternity/paternity leave (if appropriate)
Orientation plan	Other professional benefits (continuing education units, dues, licenses, parking, smartphone)
Time needed for credentialing, insurance networks	Health insurance, retirement
	Student loan repayment

If the prospective employer does not offer a formal contract, asking for confirmation in writing of offered remuneration and job specifics is wise. If the midwife is asked to sign a contract, it is wise to consult with an attorney. Even if a contract is considered non-negotiable, the midwife should thoroughly understand the content prior to signing it. **Table 2-8** provides a list of topics that generally should be negotiated prior to accepting a position and that should appear in a contract.[39,40]

Table 2-8 Topics Usually Found in a Contract

Title of position
Responsibilities, including scope of practice, currency of credentials, expectations of volume and hours

Compensation and benefits, including bonuses, productivity, professional/business expenses, tuition reimbursement, health and malpractice insurance, and paid time off
Duration and requirement for renewal of employment/contract
Reason for termination by employer and/or employee
How to alter or update the contract
Additional Topics That May Be Included
Non-compete clause[a]
Partnership arrangements (buying in or out of a practice)
Termination without cause [a]
Formulae (for bonuses, productivity, quality-based, patient satisfation, and profit-based)
Ownership of records upon dissolution/termination

[a] Not recommended but often included and may be non-negotiable.

Based on Buppert C. *Nurse Practitioner's Business Practice and Legal Guide.* 6th ed. Burlington, MA: Jones & Bartlett Learning; 2018[39]; Slager J. *An Administrative Manual for Midwifery Practices.* 4th ed. Washington, DC: American College of Nurse-Midwives; 2016.[40]

The Midwife as an Entrepreneur

Most midwives consider midwifery to be a vocation. Thus, it can be challenging to think of midwifery as "a business"—yet all midwives need to understand the basic principles of running a successful business. There is a growing need for midwives to become accomplished administrators and business managers.

Many midwives have, either independently or in groups, become business owners. The opportunity to avoid the limitations imposed by the business model or clinical guidelines developed by others, such as physicians, hospitals, and community clinics, can be very tempting, and in some cases, it may be a necessity. While many midwifery-owned businesses have succeeded in spite of inadequate planning or limited resources, the advice offered by successful entrepreneurs is consistent—namely, consult experts, invest in marketing, develop competence in billing, and collect data. Each of these aspects of running an independent midwifery practice is an important factor that can facilitate long-term success.

Business Advice from Experts

It is unwise to open a business without seeking the expertise of, at a minimum, an attorney and an accountant. The legal structure of a midwifery business (e.g., sole proprietorship, partnership, or limited liability company) will have short- and long-term personal and financial consequences. Midwife business owners should be experts on the laws and regulations that govern midwifery practice, but should also know how the laws governing medical practice, the corporate practice of medicine, and pharmacy regulations might affect their plans. Midwives providing care during out-of-hospital births must comply with health department regulations, birth center requirements, building codes, and a variety of business regulations. Midwives who employ others must determine how they will compensate those

employees and follow the relevant employment tax codes and antidiscrimination policies. Beyond malpractice insurance coverage, new business owners are often surprised to learn how many insurance policies need to be purchased and how many business contracts need to be finalized. In all of these areas, good advice can save money, protect investments, and enable midwives to provide high-quality care for women.

Preparing a business plan and seeking guidance from an accountant on the costs of doing business provide clarity for all involved and are requirements when seeking loans to help establish a business. Common elements found in a business plan are listed in **Table 2-9**.[40] The time spent attending to details and establishing a reporting system that provides regular feedback on revenues versus expenses is a good investment, as such a system provides a way to measure success for the entire team and relieves the pressure when the unexpected happens.

Plans (marketing, operating, and financial)	
Anticipated team and schedule	

Based on Slager J. *An Administrative Manual for Midwifery Practices.* 4th ed. Washington, DC: American College of Nurse-Midwives; 2016.[40]

Given that independent business ownership is valued highly in the United States, many types of support exist for small business owners, including information on how to formulate business plans and where to apply for small business loans. Midwives who are business owners often agree to mentor the next entrepreneur. The Business Section of the ACNM Division of Standards and Practice is committed to sharing information, providing support to midwives interested in the business aspects of midwifery practice, and increasing the number of midwife-owned services. The Business Section partners with ACNM to sponsor the annual conference Midwifery Works, and it has published an *Administrative Manual for Midwifery Practices*.[40] The American Association of Birth Centers also offers workshops on how to open a birth center, where many of these concepts are covered in depth. Other business guides exist in areas outside of midwifery, which may provide additional useful information.[39]

Midwifery services that are not independent businesses still have business and administrative work that must be addressed. No matter the number of employees, a midwifery service has to reach an agreement on scheduling, compensation, records management, monitoring of financial statements, negotiation of collaborative agreements, peer review, and strategies to handle personal and professional adversity. While responsibilities for the success

of the service are shared, there needs to be a designated leader or service director, who serves as the primary contact, assumes responsibility for participating on department or corporate-level committees, is able to describe the success of the service in corporate terms, and knows how to move an agenda forward within the organization. Midwives place a high value on building relationships with women and on positive feedback from the individuals for whom they provide care. Those skills can be extrapolated into the business arena and will serve the midwives well.

Data Collection

Midwives should not forget the lessons learned from Mary Breckenridge, who gathered data about the population she wanted to serve prior to opening the Frontier Nursing Service in 1925. Ms. Breckenridge understood the power of data: baseline descriptive data before opening a service, descriptive and outcome data from the first and every subsequent day of operation, analysis of data to identify relevant findings, and dissemination of the findings. A number of readily accessible mechanisms for collecting and collating practice-specific and national data exist that describe the care provided by midwives. Members of ACNM can join in the ACNM Benchmarking Project,[41] which allows participants to examine their practices and compare them to other like practices across the United States. The MANA Division of Research, with its MANA Stats system, and the American Association of Birth Centers, with its Perinatal Data Registry (PDR), both have developed web-based data collection tools that can be used by individuals and contribute to a national database on the outcomes of midwifery care in all settings.[42,43]

Marketing

Many advisors encourage early attention to a marketing plan. Without a coherent, consumer-friendly message about the services offered and an identified medium for reaching the target population, the business may not have enough clients to sustain itself. Not every practice can cover the cost of a logo and four-color brochures, but all midwives can develop marketing skills. For example, the organized, scientific, lecture approach may intimidate some women, while others may look for messages that midwifery practice is evidence based and provides adequate safeguards in the event of major complications.

Today social media may be the most effective, and least expensive, marketing strategy. Women now expect practices to have an up-to-date website. Regular tweets from midwives can remind women of healthy behaviors. Facebook allows for a robust conversation among women about health issues. To be successful, practices should engage in a variety of social media, while maintaining awareness of all of their clients' privacy.[44,45]

Professional organizations are often a source of marketing advice and materials. Several organizations are involved in national marketing campaigns that can be adapted to local settings, such as the *ACNM Healthy Birth Initiative* (summarized in **Table 2-10**).[46]

Table 2-10	**ACNM Healthy Birth Initiative: Instruments for Use in Practice**[a]

Audience	Component
For midwives and other providers	An interactive online toolkit named *Tools for Optimizing the Outcomes of Labor Safely* (BirthTOOLS), which focuses on promotion of physiologic birth. The toolkit includes the evidence, resources, protocols, and other materials.
For women	Free handout titled *Normal, Healthy Childbirth for Women and Families: What You Need to Know.* Available in Spanish and English. Designed to help consumers understand and promote evidence-based maternity care.
For hospital policymakers, payers, and other organizations	Free handout titled *Birth Matters,* which provides an overview of implementation of strategies to promote physiologic birth from their perspective.

Abbreviation: ACNM, American College of Nurse-Midwives.

[a] Several professionally printed handouts are available for a fee from ACNM.

Based on American College of Nurse-Midwives. Healthy Birth Initiative. Available at: http://www.midwife.org/ACNM-Healthy-Birth-Initiative. Accessed March 28, 2017.[46]

Billing for Services

A midwifery practice cannot continue to exist without financial stability. One of the first financial lessons in the healthcare business is that what is billed for a service is never what the insurance company will pay. Actual reimbursement rates are always lower—a factor that should be taken into consideration when calculating a budget. Whenever the services provided by a midwife are billable, the midwife must clearly document the services provided and complete the steps needed to initiate the billing process. The midwife is responsible for fulfilling the requirements for documentation that support the billing codes. For example, the amount paid for an examination will vary based on the intensity of the examination as measured by the number of systems included in the physical assessment, the types of problems identified, and the amount of time spent providing and coordinating care. If this content is not thoroughly documented in the healthcare record, payment may be reduced or even denied.

However the billing is performed, the owner(s) of the practice is (are) responsible for establishing a system of checks and balances that monitors the accuracy and timeliness of the billing process and limits the opportunity for embezzlement or insurance fraud. The time and money spent establishing a viable healthcare record and billing systems are necessary outlays to ensure the ongoing success of the business. Even midwives who are employees should be informed about the business revenue and business expenses so they will be well informed about the financial stability of the practice.

Other Roles for the Modern Midwife

Modern midwives usually fulfill multiple roles at any one time. Some of these roles not only promote the care of women and newborns, but also support and advance the profession itself. Among these roles are those of being a policymaker, an educator, and a team member. Any or all of these roles may be assumed as a midwife provides direct care to women and newborns.

The Policymaker

The building blocks of the midwifery profession (standards for education, certification, and practice) are key policy decisions with far-reaching influence. Federal, state, and institutional policies determine which healthcare services and birth settings are available to women as well as who will be reimbursed and at what rate. Which education programs receive government funding to support faculty and students is also a matter of policy. Hospitals, clinics, and employers all write policies that influence access to and provision of midwifery care. With so much at stake for the profession and the women cared for by midwives, every midwife needs to be knowledgeable about and engaged in policymaking processes.

Professional organizations remain dependent upon a high volume of work from members to keep policies relevant. Meeting the policy needs of the profession primarily represents a labor of love and a dogged determination to turn a vision into reality.

Many of the midwives who successfully work in policy did not initially see the need for this work, doubted their abilities, or hoped someone else would do it.[47] It is reassuring to know that becoming a policymaker is a learned behavior; thus, the midwifery profession is filled with successful midwife role models, and guidance on how to make this transition is available (**Table 2-11**).

Table 2-11 How to Influence the Policymaking Process: Volunteer, Observe, and Practice

Institutional policies: Write policies for your midwifery practice, hospital, and/or local midwifery organization.
Is there a template to follow?
What must be done to have the policy approved?
Legislative policies: Observe legislative policy in action by attending a hearing that addresses a regulatory issue that affects your practice.
Who seems most effective and why?
What is common etiquette and the standard for appearance?
Was the speaker effective? How did you know?
How did the committee respond?
Identify a mentor.
Come prepared and speak a language the audience can understand.
Create the draft for discussion so others have to respond to your ideas.
Stay on topic.
Know your strengths.
Offer a lived experience.
Be the voice of a midwife or support a woman or family who agrees to speak.
Know your opposition and do not attend alone.

Leave the door open for your return.
- Get help preparing statements.
- Make friends in the room.
- Defer to other experts.

If you can't do policy, support your colleagues who can do this work, including financially.

Modified with permission from Williams DR. We need to say in unison: we are midwives and we do policy! [Editorial]. *J Midwifery Womens Health.* 2008;53(2):101-102.[47] © 2008, with permission from Wiley.

In spite of many past successes, much policy work remains to be done in relation to midwifery. Some physician associations are opposed to laws that recognize advanced practice clinicians and midwives as independent providers; instead, they advocate for physician supervision. Many state laws governing the practice of midwifery need to be changed to permit independent practice. Major decisions are also looming:

- Should CNMs seek more midwifery practice acts that are separate from nursing and include their CM colleagues or stay under the advanced practice registered nurse (APRN) umbrella?
- Can CNMs/CMs and CPMs be licensed under the same practice act?
- Should CPMs be required to earn a college degree?
- Should CNMs/CMs be required to earn a doctoral degree?
- Will the U.S. Congress pass healthcare legislation that moves the profession forward or backward? (Either outcome is always a possibility.)

The Educator

All midwives are educators. Policymakers, potential employers, and consumers need to learn what is unique and valuable about the midwifery approach to care. Many women seek out midwives because they want to learn more about how to care for their own bodies and how to safely prepare for puberty, pregnancy, menopause, and all the points in between. Consumer-oriented materials often are used for this purpose, and many materials are being written by midwives. For example, *JMWH* regularly publishes a health education handout series titled *Share with Women*. These copyright-free handouts, which are targeted to women, review important clinical topics using appropriate language and illustrations for all levels of health literacy. The handouts are also available in Spanish.

Because many midwives are committed to "midwifing" students while these neophytes develop skills in the cognitive, affective, and psychomotor domains, the midwifery profession continues to flourish. The legacy of midwifery also depends on socialization of midwifery students into the role and responsibilities of the midwife. For those who choose an academic career, there are more than 40 midwifery education programs accredited by ACME with numerous midwives on faculty. Midwives who serve as faculty for schools of nursing and medicine have a unique opportunity to prepare the next generation of healthcare providers who respect women's healthcare decisions, understand that midwifery care occurs in a variety of settings, and welcome the opportunity to collaborate with midwives.

The Interprofessional Team Member

All healthcare providers work within a healthcare system that includes professionals who have different scopes of practice, different professional cultures, and different professional roles. Being a team member in the healthcare system does not imply assumption of a subservient role: In some situations the midwife is the team leader, and in others the midwife is a colleague on an interprofessional team. The factors that make interprofessional relationships work well are critically pertinent when a woman develops complications or conditions that extend beyond the scope of midwifery practice. Although it has long been recognized that interprofessional teams provide better care than single-disciplinary groups for individuals with complex healthcare needs,[48,49] interprofessional collaboration and communication have only recently been the focus of research, education, and clinical initiatives.[50,51] Guiding principles of interprofessional team–based care are summarized in **Table 2-12**.

Table 2-12	Guiding Principles of Team-Based Care
The team has a shared vision.	
Role clarity is essential to optimal team building and team functioning.	
All team members are accountable for their own practice and to the team.	
Effective communication is key to the creation of high quality teams.	
Team leadership is situational and dynamic.	

Based on Jennings J, Nielsen P, Buck ML, et al. Executive summary: collaboration in practice: implementing team-based care: report of the American College of Obstetricians and Gynecologists' Task Force on Collaborative Practice. *Obstet Gynecol.* 2016;127(3):612-617.[51]

In the 1999 ground-breaking report from the Institute of Medicine (IOM), *To Err Is Human*, it was estimated that 45,000 to 98,000 individuals die each year in U.S. hospitals due to healthcare errors.[52] Subsequent safety reports have highlighted poor communication and inadequate team coordination as the source of many of these errors. For example, a Joint Commission sentinel event analysis on preventing infant death and injury during birth identified communication problems as the root cause of the healthcare delivery error in 72% of the cases analyzed.[53] In the same analysis, 55% of the organizations studied cited organizational culture, including "hierarchy and intimidation, failure to function as a team, and failure to follow the chain-of-communication," as commonly encountered barriers to effective communication and teamwork.[53]

In the years following these publications, much work has been done to identify ways to foster and support teamwork in healthcare delivery. Successful interprofessional collaboration in care of pregnant women, for example, has been associated with improved outcomes, a high degree of maternal satisfaction, fewer cesarean sections, and lower costs.[54]

According to the International Confederation of Midwives' (ICM) *Essential Competencies for Basic Midwifery Practice*, "The midwife . . . works collaboratively (teamwork) with other health workers to improve the delivery of services to women and families."[55] Moreover, "[t]he midwife has the skill and/or ability to . . . identify deviations from normal during the course of

pregnancy and initiate the referral process for conditions that require higher levels of intervention."[55]

ACNM recognizes that midwives are independent practitioners who function within a complex healthcare system, which includes collaboration with multiple healthcare professionals, to ensure the health and safety of women and their newborns.[56] The levels of collaborative management as defined by ACNM include consultation, collaboration, and referral, and the definitions for each of these levels often serve as guidelines for similar language within state laws and hospital bylaws. While the ACNM definitions address the midwife–physician relationship, the expertise of many other healthcare professionals may be needed to provide the best care possible. It is imperative that all members of the team understand their role with any particular individual (**Table 2-13**).[57]

Table 2-13 The Continuum of Collaborative Management in Midwifery Care

Level of Collaborative Management	Definition	Primary Responsibility for Care	Midwife's Role	Collaborator's Role	Comments
Consultation (with a provider of any specialty)	"The process whereby a CNM or CM seeks the advice or opinion of a physician or another member of the health care team."	Midwife	Primary provider	Advisor/consultant	Prepare for the consultation. Know the woman's health history. Review the basics for management of the diagnosis or problem. Understand the social and psychosocial factors underlying her health. Understand the practice setting and scope of practice. Remember the Midwifery Management Process.
Collaboration	"The process whereby a CNM or CM and physician jointly manage the care of a woman or newborn who has become medically, gynecologically, or obstetrically complicated."	Co-management (depending on the severity of the complication, the midwife may remain the primary care provider)	Normal processes, coordination of care, continuity with the individual	Care for the maternal, gynecologic, or neonatal complications	Use interprofessional communication techniques such as SBAR and closed-loop communication. Clearly delineate roles to ensure all aspects of the POC are considered. Communicate with the woman and her family about the relationship.
Referral[a]	"The process by which the CNM or CM directs the client to a physician or another health care professional for management of a particular problem or aspect of the client's care."	Physician or other referral provider	Coordination of care, timely and full transfer of care, continuity of services	Assumes the primary responsibility for care of the individual	Ensure that referral/transfer is the best POC for the individual. Ensure that the woman understands that she has been transferred to another provider's care and that she has access to appointment and contact information. Consider the potential problem of abandonment of the woman and/or "punting" of difficult-to-care-for women. Use interprofessional communication techniques such as the handoff.

Abbreviations: CM, certified midwife; CNM, certified nurse-midwife; POC, plan of care; SBAR, Situation, Background, Assessment, Recommendation.

[a] Referral in this continuum refers to transfer of care. Referral in the context of insurance is providing an individual with a reference to a specialty provider.

Based on American College of Nurse-Midwives. Position statement: collaborative management in midwifery practice for medical, gynecologic, and obstetric conditions. 2014. Available at: http://www.midwife.org/ACNM/files/ACNMLibraryData/UPLOADFILENAME/000000000058/Collaborative-Mgmt-in-Midwifery-Practice-Sept-2014.pdf. Accessed June 3, 2017.[57]

The 2011 ACNM and American College of Obstetricians and Gynecologists (ACOG) *Joint Statement of Practice Relations Between Obstetrician-Gynecologists and Certified Nurse-Midwives/Certified Midwives* declares that "health care is most effective when it occurs in a system that facilitates communication across care settings and among providers."[58] NACPM and MANA have published documents that address the relationship between CPMs and physicians.[4,59] In these documents, midwifery practice is described as autonomous and CPMs are expected to collaborate, refer, and transfer care in critical situations. Essential components

of communication and teamwork are summarized in **Table 2-14**.[60-62]

Table 2-14	Essential Components of Successful Collaboration and Teamwork[a]
Professional competence in each member of the team (common body of knowledge, shared language, similarities in treatment modalities)	
Common orientation to the woman or newborn as the primary unit of attention	
Shared mental model: every member of the team can anticipate and predict the needs of the others	
Recognition and acknowledgment of interdependence among all members of the team	
Interprofessional respect and mutual trust	
Formal system of communication between providers	
Effective communication based on the goal of reaching consensus (an interest in solutions that maximize the contributions of all parties)	
Mutual performance monitoring (identification of mistakes and provision of feedback within team to facilitate self-correction)	
Identified team leader for each situation	
Situation monitoring and adaptability as the situation changes	
Ability to shift work responsibilities as needed to under-utilized team members	

[a] This list is compiled from different analyses of essential characteristics for teams in general and for teams in specific urgent or emergency situations. It is not designed to be complete or the components placed in rank order; rather, the intent is to identify some characteristics that are essential for successful interprofessional team function. Midwives are always members of interprofessional teams.

Based on Interprofessional Education Collaborative Expert Panel. *Core Competencies for Interprofessional Collaborative Practice: Report of an Expert Panel.* Washington, DC: Interprofessional Education Collaborative; 2011[60]; Ivey S. A model for teaching about interdisciplinary practice. *J Allied Health*. 1988;17:189-195[61]; King TL, Laros RK, Parer JT. Interprofessional collaborative practice in obstetrics and midwifery. *Obstet Gynecol North Am*. 2012;39:411-422.[62]

Teamwork and communication are skills that can be learned.[63-65] Although healthcare outcomes following simulation training have not yet fully been determined, it appears that simulation training improves teamwork, team coordination, and interprofessional communication.[66-68]

The U.S. Agency for Healthcare Research and Quality (AHRQ) has developed a series of materials and training curricula, collectively titled TeamSTEPPS, that can be used in healthcare settings to help foster successful teamwork.[63,64,69] The TeamSTEPP curricula emphasize the development of four core competencies: communication, mutual support, situation monitoring, and leadership.

Communication Techniques for Successful Collaboration

Direct and deliberate communication techniques include SBAR, closed-loop communication, and the handoff. SBAR—an acronym for **S**ituation, **B**ackground, **A**ssessment, and **R**ecommendation—is a structured communication tool that has been shown to significantly improve the quality of communication between healthcare providers and to reduce errors.[67] The SBAR approach omits the nonessential elements of a woman's history, distills the most

pertinent information, and clarifies what is needed. The midwife can use the SBAR approach to obtain a consultation from a specialist (**Table 2-15**) or to communicate during an emergency (**Table 2-16**).

Table 2-15	Example of SBAR Used for a Consultation

The midwife at an office is caring for a woman who is at 33 weeks' gestation and was diagnosed earlier in the pregnancy with gestational diabetes. When reading the woman's blood glucose log, the midwife observes that more than 20% of her values are high. She calls the consulting maternal–fetal medicine physician and gives this consult using SBAR.

S: I want to consult with you about a woman with uncontrolled gestational diabetes.

B: Maria Gonzalez is a 24-year-old primigravida at 33 weeks by LMP consistent by 19-week ultrasound. Her 1-hour glucose tolerance test was 150 mg/dL and her 3-hour glucose tolerance test had two elevated values. She was sent to the diabetes education center and received diet and glucose monitoring education. Over the last 2 weeks, 20% of her values are out of range, with five fasting levels between 100 mg/dL and 110 mg/dL and five 2-hour postprandial levels higher than 150 mg/dL, the highest being 180 mg/dL. She had a reactive NST today, the fetus is size equal to dates, and her urinalysis was negative for glucose.

A: My concern is that her diabetes diet is inadequate to control glucose levels, and I believe she needs medication.

R: I would like to schedule her to see you for a consultation within the next few days.

Abbreviations: LMP, last menstrual period; NST, nonstress test; SBAR, Situation, Background, Assessment, Recommendation.

Table 2-16	Example of SBAR Used in an Emergency Situation

The midwife at a small community hospital is caring for a woman who is bleeding heavily immediately after giving birth. She has called for physician assistance from a provider in the next room. When the physician arrives, the midwife says:

S: This woman is having a postpartum hemorrhage.

B: Marta gave birth to her fifth child 15 minutes ago over an intact perineum. Her total EBL is 800 mL. She has received 40 IU of oxytocin (Pitocin), 0.2 mg of ergonovine (Methergine), and 800 mcg of misoprostol per rectum (Cytotec). The placenta appeared intact, and there are no clots in the lower uterine segment.

A: She has severe uterine atony, and I think I feel some placental tissue in the anterior portion of the fundus.

R: I need you to put on gloves and assist me.

Abbreviations: EBL, estimated blood loss; SBAR, Situation, Background, Assessment, Recommendation.

In closed-loop communication, the midwife directs the message to a particular team member, the team member repeats the order or request aloud, and the midwife confirms that the team member heard correctly. This communication approach is particularly important during times of stress, as it allows the entire team to hear the orders and correct any errors before the orders are executed. Closed-loop communication tools such as the *call-out* and the *check-back* can be used to communicate critical information to all members of the team, thereby allowing them to anticipate what will be needed next. Use of such instruments also requires that team members communicate what they intend to do and have done with the information.

When the care of a woman or a neonate needs to be transferred to another provider, especially for a higher level of care, a formal note should be written in the health chart and

shared with the new provider. The goal of this communication is to give the new provider all of the pertinent information needed to safely care for the woman and her family. In several of the chapters in this text, *critical elements* are listed for conditions that typically require a transfer of care. In some situations, a midwife may receive a transfer from another provider. In that case, the midwife who receives the transfer should communicate, either verbally or in writing, with the referring provider to acknowledge that the woman has been seen and provide a summary of her course of care. **Table 2-17** provides an overview of the content of a transfer or handoff note and the critical elements it should contain.

Table 2-17 Sample Critical Elements for a Transfer Note from Out-of-Hospital to Inpatient Care

Record time and destination, method of transportation, and who is accompanying the woman/newborn when care is transferred
Identify the woman/neonate and the transferring provider; as well as the receiving provider
The critical elements are customized to the individual and the situation but generally include:
1. Risk factors for the current situation/disorder requiring transfer
2. Signs and symptoms indicating need for transfer
3. Care provided before transfer: procedures and results; laboratory results or if pending; medications (dosage, route and time of last dose); response to treatment
4. Assessment/diagnosis of the situation
5. Summary of the rationale for the transfer Request for information about the treatment plan for follow-up

Communication skills such as SBAR, closed-loop communication, and the handoff are like any clinical skill: They must be adapted to individual settings and practiced until they become second nature.

The Researcher and Research User

Midwifery has a long tradition that includes learning by watchful waiting; sharing empirical knowledge via oral traditions; defining and protecting the normal, nonmedicalized birth process; and actively challenging "the evidence." These characteristics have served women well, especially when research has validated the midwifery approach. Examples where midwives have had a strong influence in the evolution of best practices include elimination of routine episiotomies,[70] redefinition of the Friedman labor curve,[71] promotion of early and prolonged breastfeeding for neonatal and maternal health,[72] delayed cord-clamping,[73] immediate skin-to-skin contact between mother and newborn,[74] water immersion during labor,[75] an alternative pain assessment tool for laboring women[76] and nonpharmacologic methods of pain control.[77]

A 2017 ACOG Committee Opinion, *Approaches to Limit Intervention During Labor and Birth*, has the potential to decrease what has come to be seen as common disagreements between some physicians and midwives regarding labor management.[78] Acknowledging that

"many common obstetric practices are of limited or uncertain benefit for low-risk women in spontaneous labor," this document makes 11 evidence-based recommendations intended to decrease unnecessary interventions and increase maternal and family satisfaction. These recommendations closely align with ACNM recommendations.[79]

Sackett et al. concisely defined evidence-based practice (EBP) in 2000 as the "integration of the best research evidence with clinical expertise and patient values."[80] Not all midwives need to actively conduct research, but all need to understand relevant research and implement evidence-based care. The call for systematic use of evidence in the field of caring for pregnant women is often credited to the 1989 publication of the two-volume book, *Effective Care in Pregnancy and Childbirth*.[81] In this ground-breaking treatise, the authors carefully evaluated existing research articles and identified those clinical practices supported by research as well as those practices that the evidence did not support.

Several databases that summarize the most recent evidence on a multitude of clinical topics are available to women's healthcare providers. One important evidence-based database is the Cochrane Library. Cochrane Reviews are systematic reviews of primary research in human health care and health policy and are widely recognized for the quality of the reviews.[82] Other sources of research that midwives often use include PubMed, the Up-to-Date Database, and DynaMed.

When assessing research data and results, it is important to remember that "not all evidence is created equal." Once all the research data have been gathered, the findings need to be compared and contrasted. Evidence then is evaluated to determine its strength.[83] Several ratings criteria have been developed that evaluate the strength and quality of research findings. One of the most commonly used rating scales is that used by the U.S. Preventive Task Force, which are listed in the *Health Promotion Across the Lifespan* chapter in this text.

Systematic reviews of the literature have documented that midwifery-led care (care in which the primary provider is the midwife) for essentially healthy women is equivalent to the care provided by physicians. For several outcome measures midwifery care has been found to be associated with better outcomes compared to physician care. A 2008 Cochrane meta-analysis reviewed 11 trials including 12,276 women, and found several statistically significant differences in outcomes for those women who received midwife-led care.[84] All of the studies included in this systematic review were randomized, controlled trials; in addition, the studies were not limited to one country. The findings noted that midwife-led care resulted in fewer prenatal hospitalizations, less use of regional analgesia, fewer episiotomies, and fewer instrument deliveries. In addition, women who received care in a system of midwife-led care were more likely to experience no intrapartum analgesia/anesthesia, a spontaneous vaginal birth, feeling in control during childbirth, attendance at birth by a known midwife, and initiation of breastfeeding. Finally, the newborns of women who had midwife-led care were more likely to have a shorter length of hospital stay. The authors concluded that "most women should be offered midwife-led models of care and women should be encouraged to ask for this option although caution should be exercised in applying this advice to women with substantial medical or obstetric complications."[84]

Similar results were highlighted in a 2011 systematic review that examined outcomes for

APRNs in the United States. For the purposes of this study, the authors defined certified nurse-midwives as a type of APRN, and CNM birth outcomes from 1990 to 2008 were examined separately from those of other groups of providers who were not CNMs.[85] This review summarized the results from all levels of studies, including observational studies, and studies were limited to the United States. A high level of evidence was found that certified nurse-midwives, when compared to physicians, had lower rates of cesarean section birth, episiotomy, operative birth, labor analgesia, and perineal lacerations, and equivalent rates of labor augmentation, low Apgar scores, and low-birth-weight infants. The systematic review also demonstrated a moderate level of evidence that care by nurse-midwives is associated with lower rates of epidural use and induction of labor, comparable or higher rates of vaginal births, comparable or lower rates of newborn intensive care unit admissions, and higher rates of breastfeeding among women who received care from these professionals.[85]

In 2016, the Cochrane Pregnancy and Childbirth Group published a review comparing midwife-led continuity models and other models of care,[86] updating the 2008 systematic review conducted by Hatem et al.[84] Fifteen trials involving 17,674 women were reviewed. In all trials, the pregnant women were randomly assigned to midwife-led continuity models of care or other models of care. In short, women who received the midwife-led continuity model of care were less likely to experience intervention and more likely to be satisfied with their care with at least comparable rates of adverse outcomes compared to women who received other models of care. The major findings from this updated Cochrane Review are summarized in **Table 2-18**.

Table 2-18 Systematic Review of Midwife-Led Continuity of Care, 2016

Outcome or Subgroup Title	Number of Studies	Number of Participants	Relative Risk (95% Confidence Interval)
Primary Outcomes: Significant Risk Reductions Found			
Regional anesthesia	14; high quality	17,674	RR = 0.85 (0.78–0.92)
Instrumental vaginal birth	13; high quality	17,501	RR = 0.90 (0.83–0.97)
Preterm birth: less than 37 weeks' gestation	8; high quality	13,238	RR = 0.76 (0.64–0.91)
Less all fetal loss before and after 24 weeks' gestation plus neonatal death	13; high quality	17,561	RR = 0.84 (0.71–0.99)
More Likely to Experience			
Spontaneous Vaginal Birth	12; high quality	16,687	RR = 1.05 (1.03–1.07)
No difference between groups for caesarean births and intact perineums			
Secondary Outcomes: Significant Risk Reductions Found			
Amniotomy	4	3253	RR = 0.80 (0.66–0.98)
Episiotomy	14	17,674	RR = 0.84 (0.77–0.92)
Fetal loss less than 24 weeks' gestation and neonatal death	11	15,645	RR = 0.81 (0.67–0.98)
More Likely to Experience			
No intrapartum analgesia or anesthesia	7	10,499	RR = 1.21 (1.06–1.37)
Longer length of labor	3	3328	RR = 0.50 (0.27–0.74)
Attended at birth by known midwife	7	6917	RR = 7.04 (4.48–11.08)

Based on Sandall J, Soltani H, Gates S, Shennan A, Devane D. Midwife-led continuity models versus other models of care for childbearing women. *Cochrane Database Syst Rev.* 2016;4:CD004667. doi:10.1002/14651858.CD004667.pub5.[86]

In addition to these large reviews, numerous other published research studies have focused on specific practices of midwives that may account for differences in maternal and neonatal outcomes. In 2012, ACNM updated a PowerPoint slide set titled "The Pearls of Midwifery," which translates the latest evidence in a manner that can be easily communicated to other providers, or to women and their families.[79]

Midwifery as a Worldwide Profession

While midwives maintain their commitment to provide individualized care responsive to the needs of the woman and newborn, they are also recognized as key players in the global community of healthcare professionals who significantly improve the lives of mothers and babies.[87] This expanded allegiance—from the individual, to the profession, to evidence-based practice, to women wherever they need care—is reflected throughout this text.

For many years, midwives in the United States and many countries around the world were undervalued by the policymakers who designed and funded healthcare systems. Most would agree that this low status, and the accompanying low pay, was a direct reflection of the value that policymakers assigned to women and women's health care. In a trajectory that closely follows the emancipation of women, midwives have found their collective voice, established professional standards for education and practice that compare favorably to their physician colleagues, and proved their value to the preservation of a healthy modern society.

While the rate of public acceptance and legal recognition of midwives as professional and autonomous healthcare providers has varied from state to state and from country to country, the global community of midwives is increasingly united around the need to earn and seek this recognition. The International Confederation of Midwives (ICM) is a global federation of midwifery associations that has worked for more than 100 years to support, represent, and strengthen professional associations of midwives throughout the world.

ICM initially provided a much-needed forum for midwives to learn from each other and to expand access to midwifery care. Nevertheless, it was not until 1972 that the confederation agreed to set standards for who should be able to use the "midwife" title. The original focus of this organization—to increase the number of midwives—reflected an understanding that too many women and babies were dying because they were giving birth unattended. Over time, it became clear that a lack of common standards for the preparation and practice of midwives could also put the lives of women at risk.

Many midwives feared that setting standards for midwifery education and practice would isolate traditional midwives and decrease access to care. Others emphasized the value for midwives of setting their own standards and using these standards as the justification to fund education for midwives, especially in countries with limited resources. In 1972, the ICM published its first *Definition of a Midwife*; it was most recently updated in 2011. In 2010, ICM published the *Essential Competencies for Basic Midwifery Practice*; it was most recently updated in 2013.[88]

Between 2008 and 2011, the International Confederation of Midwives accepted the difficult challenge of formally describing the three pillars of midwifery: education, regulation, and essential core competencies for midwifery practice. These core ICM documents have an important impact on midwifery in all nations.[55,88] For example, the Midwifery Education, Regulation, and Association work group,[5] a collaboration of the seven midwifery professional associations in the United States have worked together to adapt the ICM documents for midwifery in the United States. The 2015 publication of *Principles for Model U.S. Midwifery Legislation and Regulation* is one of the outcomes of this collaboration.[5,89] ICM now publishes multiple gap analysis tools and curriculum guidelines designed to assist midwifery

associations and policymakers in actualizing their support for professional midwifery practice. Since its launch in the early 1900s, the ICM has expanded to include, as of 2016, 132 midwifery associations from 113 countries, representing an estimated 500,000 midwives worldwide.[90]

The American College of Nurse-Midwives has been a member of ICM since 1956. The ACNM and many CNMs/CMs have made significant contributions to the ICM mission by strengthening midwifery associations globally, publishing training materials for midwives such as the *Life-Saving Skills Manual for Midwives*[91] and *Home-Based Skills Manual for Midwives*,[92] and advocating for reduction of needless maternal deaths.

Midwives frequently seek ways to share their expertise globally, and they are often sought as team members on international projects. **Appendix 2A** provides information to help prepare midwives for such projects—projects that are meaningful for women in other countries as well as for the midwives themselves.

Conclusion

In the twenty-first century, midwifery is an evolving profession with a strong, inspirational foundation; a mature infrastructure to promote policies that improve access to high-quality midwifery care; highly educated individuals who are defining best practice; and plenty of unfulfilled potential. Midwives have demonstrated their capacity to do the hard work of profession building, to critically evaluate traditional models of care, to challenge policies based on flawed research, and to pursue a more just healthcare delivery system. How the profession changes and grows will reflect who the new midwives are, what brings them to the profession, who educates them, and how much they are willing to give to individual women, to the profession of midwifery, and to the process of creating a world where all women receive the best care possible.

Organization	Description	Webpage
American Association of Birth Centers (AABC)	A multidisciplinary membership organization dedicated to the birth center model of care.	http://www.birthcenters.org
American College of Nurse-Midwives (ACNM)	Professional organization for certified nurse-midwives and certified midwives in the United States. The Hallmarks of Midwifery can be found on this site.	http://www.midwife.org http://www.midwife.org/ACNM/files/ACNMLibraryData/UPLOADFILENAME/00000000
American College of Obstetricians and Gynecologists (ACOG)	Founded in 1951, ACOG is the specialty's professional membership organization dedicated to the improvement of women's health. Interdisciplinary collaboration	https://www.acog.org http://www.acog.org/Resources-And-Publications/Task-Force-and-Work-Group-Repo Based-Care
American Nurses Association (ANA)	ANA advances the nursing profession and advocates on	http://nursingworld.org

	healthcare issues that affect nurses and the public.	
American Public Health Association (APHA)	A champion for the health of all people and all communities, AHA works to strengthen the profession and to speak out for public health issues and policies supported by science.	https://apha.org
Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN)	AWHONN works to improve and promote the health of women and newborns and to strengthen the nursing profession.	http://www.awhonn.org
Childbirth Connection	This organization was founded in 1918 as the Maternity Center Association, is now a program in the National Partnership for Women and Families. It works to improve the quality and value of maternity care through consumer engagement and health system transformation. Childbirth Connection promotes safe, effective, and satisfying evidence-based maternity care	http://www.childbirthconnection.org

	and is a voice for the needs and interests of childbearing families.	
Coalition for Quality Maternal Care (CQMC)	In April 2011, nine national professional, consumer, and human rights organizations announced the formation of this coalition to champion the urgent need for national strategies to improve the quality and value of maternal and newborn health care in the United States.	http://www.midwife.org/Coalition-for-Quality-Maternity-Care
Home Birth Summit	In 2011, 2013, and 2014, the Home Birth Summits convened a multidisciplinary group of leaders, representing all stakeholder perspectives, to address their shared responsibility for care of women who plan home births in the United States.	http://www.homebirthsummit.org
International Confederation of Midwives (ICM)	This global federation of midwifery associations has worked for more than 100 years to support, represent, and strengthen professional associations of midwives	http://internationalmidwives.org

	throughout the world.	
Lamaze International	Established in 1960, and redefined in 2001, Lamaze dramatically changed from being a method for giving birth to a philosophy that provides the foundation and direction for women as they prepare to give birth. This organization's mission is to advance safe and healthy pregnancy, birth, and early parenting through evidence-based education and advocacy.	https://www.lamazeinternational.org
Midwifery Business Network (MBN)	A collaborative of CNMs and CMs who, for more than 30 years, have supported entrepreneur midwives. In 2015, the network was integrated into the Business Section of the American College of Nurse-Midwives' Division of Standards and Practice.	http://www.midwife.org/index.asp
National Association of Nurse Practitioners in Women's Health (NPWH)	NPWH works to ensure the provision of quality primary and specialty health care to women of all ages by women's health	https://www.npwh.org

	and women's health–focused nurse practitioners.	
National Partnership for Women and Families (NPWF)	Founded in 1971 as the Women's Legal Defense Fund, NPWF promotes fairness in the workplace, reproductive health and rights, access to quality, affordable health care, and policies that help women and men meet the dual demands of work and family.	http://www.nationalpartnership.org
National Women's Health Network (NWHN)	Feminist health activists who use policy analysis as a tool. Starting in 1940 with a protest about the risks of estrogen, NWHN has sought to bring the voice of people concerned about women's health to the decision makers who create and implement health policies.	https://nwhn.org https://www.womenshealthnetwork.com
Our Bodies Ourselves (OBOS)	Since its founding in 1969, OBOS has sought to advance health and human rights within a framework of values shaped by women's voices and a	http://www.ourbodiesourselves.org

	commitment to self-determination and equality.	
White Ribbon Alliance	International organization with a mission to catalyze and convene advocates who campaign to uphold the right of all women to be safe and healthy before, during, and after childbirth.	http://whiteribbonalliance.org

APPENDIX

2A

Worksheet for Engaging in Global Midwifery

JOYCE E. THOMPSON

© hakkiarslan/iStock/Getty Images Plus/Getty

This appendix is designed for midwifery students as well as midwives who are interested in sharing their expertise in geographic settings outside of their own state/country. The following key steps are intended to help a midwife decide whether international work is personally appropriate and if so, how to actualize that desire. This process takes times and experience. Enjoy the journey!

The first two steps involve personal reflection. The next seven steps involve pragmatics of engaging in global work as a midwife.

Step 1: Reflect on Your Beliefs, Values, and Characteristics

Take time to answer these questions: They are designed to help you learn about yourself and how you view working in cultures other than your own and with other team members. Be honest with yourself. This reflection can help you decide if international work is for you.

A. Values

What are the five most important values that guide my life, my actions, and my decisions?

Why are these values important to me?

Which basic human rights do I believe should be accorded to women and young girls? Are these consistent with my important values?

What do I value about the profession of midwifery and professional midwives?

Upon reflection, are my values congruent with international midwifery work? Do I need to rethink my long-term plans?

B. Working with Others

Which of my personality traits can contribute to positive communication with diverse individuals/cultures or detract from positive communication?

What is my usual response, both verbal and nonverbal, when I do not understand what is being said (perhaps in situations when another language is used or within my own language, such as use of slang words)?

What is my usual response, both verbal and nonverbal, when others do not understand what I am saying?

How well am I able to recognize information shared with me in confidence, and then maintain that confidence? (How trustworthy am I?)

How effective am I in gaining the trust of others in new situations?

Which experience to date have I had in living or working with those who speak a language different from my own?

Upon reflection, which traits or responses above should I strengthen and which should I change or improve?

C. Working as a Team Member

What are my dominant personality traits (e.g., like to be in charge, passive, outgoing)? How do these traits fit with a team? What is the role I usually take in a team situation (e.g., leader, member, quiet one)?

What is my usual response when I feel lacking in knowledge or experience, or am intimidated by others? Is that a useful response? If not, how can I change it?

How do I react when I am faced with a situation requiring a different approach from that I had planned to do?

What is my usual response when I am working with someone who knows more than I do?

Does it make a difference if team members are younger or older, or a different gender than mine?

How well do I work toward compromise? (Examples are important.)

What is my experience in living with decisions that differ from the ones I would have chosen in the situation?

How important is it that others follow my recommen-dations/advice?

How well do I support others in doing “for themselves” rather than doing it for them?

How do I respond to individual team members who do not follow through with agreed activities/responsibilities (do not carry their share of the work)?

Upon reflection, which traits or responses above should I strengthen and which should I change or improve?

D. How Do I Respond to Stress?

What is my usual response to being in a situation of uncertainty (e.g., new geographic place, new people)?

How do I normally deal with stress in my day-to-day living; as a midwife; when I am jet-lagged, tired, or overwhelmed?

Upon reflection, which traits or responses above should I strengthen and which should I change or improve?

E. Can I Live in a World That Is Very Different Than My Home?

Do I have any special dietary needs or healthcare needs, and have I thought about how they could be met in a variety of cultures? Would they limit my ability to be an international consultant? Explain.

Which experiences can I identify that help me understand the variety of "personal space" needs of individuals, including myself?

Have I had any experience living for longer than a few days without running water, indoor plumbing, or electricity? How did I cope?

What is the longest time I have been away from family/friends and have I ever been "homesick" or felt "lonely" when away from home?

What experience have I had in working with those who hold a different worldview than my own?

Upon reflection, which traits or responses above should I strengthen and which should I change or improve?

Step 2: Reflect on What You Have to Offer

Assuming you want to work internationally, which special talents can you provide? You want to be a help with global work, not just an observer. Sometimes you may need to sell yourself to a nongovernmental organization (NGO) or grant funder.

What are my particular areas of expertise in maternal and newborn health, family planning, and midwifery?

In which languages am I fluent?

What can I do (e.g., activities, reading, seeking support from experts) to improve my consultant competencies? (Be specific.)

What time frame will I need to complete the above activities?

Should I be a "consultant" or a "team member" of a larger group?

Step 3: Getting Organized and Ready

Once you have decided you understand and want to do global work, organization is essential. You do not simply show up in another country and plan to work.

Gain midwifery practice expertise, comfort, and confidence before you consider global work.

Learn about global midwifery initiatives, such as the role and work of the International Confederation of Midwives (ICM) and the World Health Organization (WHO).

Obtain licensure as a professional midwife in the area where the work will occur.

Consider joining a team and experiencing global work *before* even thinking you can be a formal "consultant."

Develop other areas of midwifery expertise (e.g., education, regulation, association leadership).

Step 4: Review the Proposed Project or Trip Before Accepting

When you do join a team or become a consultant, know what the position entails. Do not blindly attempt to work globally. A good project has clear, measurable, achievable, and sustainable objectives.

Who/which agency is funding the proposal and what is its track record in midwifery development and/or support?

What is the purpose of the proposal?

What are the expected outcomes and time frame? Who is responsible for each expected outcome?

Learn the language of the project (e.g., expected outcomes often are called terms of reference [TOR]).

Are the outcomes achievable within the time allowed?

Where and when will the project take place, and which language is needed?

What are the financial details, and are they acceptable for the products expected? Do I have the resources needed?

Who is responsible for logistics, including travel arrangements and visas if needed?

What are the plans for sustainability, if appropriate?

Is this a duplicate activity with other NGOs? If so, is it needed? Should I participate?

Step 5: Decide Whether Your Qualifications and Expertise Match What Is Expected

This step provides another time for you to be honest with yourself. Where do you fit within this project? Can you be a useful contributor? If you are a consultant, do you have the skills and knowledge to be successful?

What would be my role: consultant? team member? other?

Do my competencies match the needed expertise for my role?

Do I meet the agency's requirements for being a consultant or team member?

Do I have knowledge of the host country's midwifery situation?

Am I available in the time frame for consultation?

Do I have the language and communication skills expected during the consultation?

If not, how can I plan for the future?

Step 6: Planning for the Consultation Prior to Arriving in

Country

Before you leave the United States, learn about where you are going. The more you know in advance, the faster you can become a global worker or consultant in that country. You do not want to waste time in the country learning information that you already could have known.

Research all available information regarding the country and the situation for midwifery there.
Talk with other midwives who have been in the country.
Review legal regulations relating to the work you will perform.
Identify who is in charge of health care in the country (e.g., health minister).
Learn how midwives' work is integrated with the roles of other healthcare providers.
Prepare a detailed plan of work to accomplish the project objectives.
Communicate with designated contacts in the country and in the agency.
Partner with the host country midwife/association, as appropriate.
Identify and arrange for meetings with key stakeholders in advance.
Prepare materials needed for consultation (e.g., agenda for workshops, handouts, business cards).
Pack needed clothing for the climate and culture; bring a computer with appropriate electrical connections.
Confirm the travel arrangements.

Step 7: Carry Out the Project According to the Terms of Reference

Although you always should expect that some things might occur that are not planned, you also should have a clear idea of how you will proceed to meet the project objectives. This is true whether you are a member of a team or the consultant in charge.

Receive a briefing upon arrival from the country contact person.
Confirm prearranged meetings with key stakeholders and meet with them.
Carry out the detailed plan of work, adjusting it as needed to meet the objectives.
Take notes daily and keep a list of all persons contacted and reasons for any changes.
Prepare a draft report of the consultation.
Report draft findings to designated individuals prior to leaving the country, if expected.

Step 8: Prepare Final Reports

A final report is an essential component of international work. This report is facilitated if the previous steps are followed and notes are taken contemporaneously.

The final report should follow the template of the funding agency, if available. Some funders require that the final report begin with a one-page executive summary.
The report should address each expected outcome and the extent to which it was met.

The report often includes persons and places visited, along with dates, workshop outcomes, or lectures presented.
All reports need to be strategic, with an emphasis on the extent to which the expected outcomes were met, lessons learned, and recommendations for follow-up as needed.
The funder may require a separate "trip report" for travel and per diem reimbursement.
Submit an invoice, usually with the final report to the funder/agency.

Step 9: Reflect on Lessons Learned

Personal reflection after every global experience enhances your future plans. Again, be honest with yourself and learn from the experience.
What did I learn from the experience that will help me in future consultations?
Which mistakes did I make that I prefer not to repeat, and what is needed to overcome these?
Which strengths/special expertise did I demonstrate, and how will these add to future efforts in international midwifery support/consultation?
How do I plan to share my international midwifery experience with others?
If I were a team member, will I be an international consultant next? How do I prepare?

"A person's ability to choose wisely is harmed when their provider does not distinguish between personal beliefs and professional actions."

—Jan M. Kriebs

"If you have come to help me, you are wasting your time. But if you have come because your liberation is bound up with mine, then let us walk together..."

—Lila Watson, Australian Aboriginal woman, in response to mission workers

Introduction

An individual's health is influenced by five factors: genetics (30%), behavioral patterns (40%), social circumstances (15%), health care (10%), and environmental exposures (5%).[1,2] Behavioral patterns and environmental exposures are inexorably linked to social circumstances. It is now well known that social determinants of health (SDOH) have a significant impact on health, and that SDOH have the largest impact on health inequities.[1-5] Yet, worldwide, multiple social, political economic, and environmental inequities continue to contribute to significant health disparities, including preventable morbidity and mortality.[3,4]

Healthcare services can improve the health of individuals only when certain conditions are met. First, the individual must have access to healthcare services. Second, the care offered must be of good quality and based on evidence. Healthcare services are likely to be ineffective if the nonbiologic factors that affect access to and quality of care are not addressed. This chapter introduces key concepts that provide the foundation for understanding health disparities, including root causes and the roles that midwives play in mitigating health disparities. Midwifery is inherently a public health–oriented profession, and midwives have a fiduciary responsibility to seek ongoing education about these topics and application of this body of knowledge in each and every healthcare encounter.

The topics presented in this chapter include some exemplars of well-known disparities in health care. Although this chapter addresses just a few of the SDOH, this content can serve as a platform—a foundation—to help midwives identify which learning is needed to provide quality healthcare services to persons from all cultures and populations.

The first section introduces the concepts of power, privilege, and bias that affect every healthcare interaction. The second section explores the concepts of social structure and power that create SDOH inequities. Subsequent sections provide an overview of healthcare disparities and review several populations in the United States whose health is most impacted by inequity. The final sections describe the techniques used by individual midwives and the midwifery profession as a whole to address health disparities. Finally, population-based health statistics are internationally recognized as indicators of a nation's health and widely used to identify and track trends in the health status of populations. An understanding of reproductive health statistics is essential for all midwives, as these data frequently guide practice. **Appendix 3A** reviews definitions of key reproductive health statistics and explains how they are used and interpreted.

One more important caveat must be discussed before delving into the main chapter content. Language is an evolution and journey of its own, and the language used in this chapter and text is deliberately inconsistent. The term "persons of color" is used in this chapter as an umbrella term that refers to all persons who are not identified by society as white. It can be helpful to consider non-white persons together when looking at the effects of racism. However, important aspects of a person's racial, ethnic, and cultural identity can be muted when many different cultures are grouped together under one umbrella, and this is a cautionary point the reader is asked to bear in mind. Additionally, both the terms "African American" and "black" are intentionally used throughout the text to recognize that labeling persons within this social construct is challenging and imperfect. This chapter also aims to use gender-neutral language.

Due to the great diversity of gender identities, actively evolving norms about how to discuss gender on a population level, and the frequent lack of data that disaggregate the multitude of gender identities, the terms “woman” and “women” are used throughout this textbook without clarifying qualifiers. Language that refers to gender is not perfect, of course, so the reader is asked to consider the text with a critical eye and an awareness that while humans must be referred to with a word or phrase, those labels are never a comprehensive or totally accurate definition for any individual.

Social Structure: Power, Privilege, and Bias

"Society" is one of the most influential contexts within which individuals and communities exist. "Society"—that is, the organized pattern of relationships and interactions within a population—incorporates deeply embedded categories that affect each of us. These socially constructed categories and classifications reinforce hierarchical relationships between identities, such as gender, race, ethnicity, sexual orientation, socioeconomic status, religion, nationality, and immigration status. The existence of a social hierarchy privileges some identities as having implied and/or explicit power in relationship to oppressed identities.

Power is the ability to direct or influence the behavior of others, oneself, or a course of events; *privilege* exists when power unfairly advantages persons in some social categories versus others. Persons who identify with the socially dominant categories in **Table 3-1** have more privileges than do persons in the socially oppressed categories; similarly, persons in socially oppressed categories can be discriminated against or treated differently based solely on their "minority status."

Table 3-1 **Selected Categories That Are Determined by the Social Hierarchy**[a]

Category	Socially Dominant	Socially Oppressed
Gender	Cisgender male	Cisgender female, transgender, nonbinary and gender-nonconforming individuals
Race	White	People of color
Socioeconomic status	Middle and upper class	Poor, working class
Nation	Global North (including the United States)	Global South
Ethnicity	European	All other ethnicities
Sexual orientation	Heterosexual	Lesbian, gay, bisexual, queer, asexual
Religion	Christian	All other religions
Ability/disability	Able-bodies	Persons with disabilities (e.g., physical, mental, learning)
Age	Youth	Elderly people
Immigration status	Citizens	Undocumented persons, individuals with insecure documentation status, refugees, migrant workers, asylum seekers
Body size	Persons with BMI in the range 19–25 mm/kg^2	People with BMI < 19 mm/kg^2 or > 25 mm/kg^2
Language	English	All other languages

Abbreviation: BMI, body mass index.

[a] This table presents some examples of well-known social hierarchical identities that affect individuals. It is not intended to be a definitive guide to all forms of hierarchy.

An individual's social location is composed of multiple social identities and the interactions between them (e.g., race, ethnicity, gender, class, sexual orientation, age, disability/ability, migration status, religion). The individual experience of this multilayered existence reflects the

intersection of privilege and oppression at the social-structural level. Collectively, this framework is known as *intersectionality*.[6,7]

Societal privileges and discriminations grant variable and inequitable access to social, political, and economic resources, such as wages, high-quality education, safe housing and communities, and comprehensive health care. Structural, institutional, and interpersonal discrimination, in turn, contribute to health inequities. Health and health care are affected by power and privilege in society, such that individuals who experience socially dominant identities tend to have better health outcomes.

Healthcare Provider Bias

One of the ways that social hierarchy influences midwifery care is through healthcare provider bias. The social hierarchy shapes our unconscious and conscious beliefs about dominant and oppressed groups. These beliefs are referred to as *bias*, which is favor toward or prejudice against a certain person, group, or thing, typically without merit.

Bias reinforces social hierarchies, and it can result in unequal access to healthcare services and unequal rendering of quality care. This divergence often happens because there is a significant disparity between healthcare providers' *beliefs* and *actions* when interacting with individuals from social identities different than their own. Providers usually value fairness and justice, yet they may exhibit biases to the same extent as the general population and not offer equal care to all people.[8-10] Therefore, the ways in which healthcare providers perpetrate health inequities requires an examination of bias, and specifically implicit bias.

Implicit Bias in Healthcare Providers

Implicit bias is the process by which unconscious attitudes create preferences and assumptions, thereby shaping one's interactions with others and influencing behavior "without the conscious intention of the agent."[8] A provider may have few explicit biases but a high level of implicit biases. This concept explains the contradiction between healthcare providers' beliefs and actions. In essence, implicit bias results in an unintentional contradiction between the conscious desire to provide equal evidence-based care and the actual clinical decision making that occurs.[11] Multiple studies and systematic reviews have found that *implicit racial bias* adversely affects provider–client interactions, treatment decisions, treatment adherence, and healthcare outcomes.[12-14] Groups more likely to receive disparate care secondary to implicit bias are those identified in Table 3-1 as socially oppressed.

Implicit bias is difficult to address because it is unconscious. Factors such as provider stress and fatigue may increase the likelihood of the provider engaging in biased behaviors. A high cognitive load activates implicit biases in an unconscious attempt to categorize data quickly. In settings where midwives are expected to see a high volume of individuals in very short time slots, institutional approaches are needed to reduce cognitive demands, as a first step toward minimizing implicit biases.[8]

Reducing the interpersonal discrimination that results from implicit bias requires both ongoing individual examination and conscious de-biasing.[15] Recognizing the existence of one's

implicit biases is a useful starting point, but ongoing self-education about the nature of bias and triggers that evoke the biases is key to minimizing the adverse effects of implicit bias.[15] Online resources that help midwives identify implicit bias are listed in the Resources section at the end of this chapter.

Social Determinants of Health and Health Disparities

Over the last two decades, public health, medical, and nursing researchers have made significant advances in elucidating the effects of historical, social, political, and socioeconomic factors on individual and population health. As noted earlier, *social determinants of health* is the term widely used to describe these factors. SDOH comprise the wide range of factors that impact health but that have not historically been under the purview of clinical care (**Figure 3-1**).[16,17] The Centers for Disease Control and Prevention (CDC) defines SDOH as "conditions in the environments in which people are born, live, learn, work, play, worship, and age."[4] These factors can either promote good health or contribute to poor health. Research about SDOH has demonstrated that unequal distribution of power, money, and resources underlies the differences that contribute to disparities in health outcomes.[3] Because these forces are social, political, cultural, and economic in nature, clinical care alone cannot address the causes of these disparities. Attention to equity and justice in policy, structure, and culture change are required to address and eliminate these inequities.

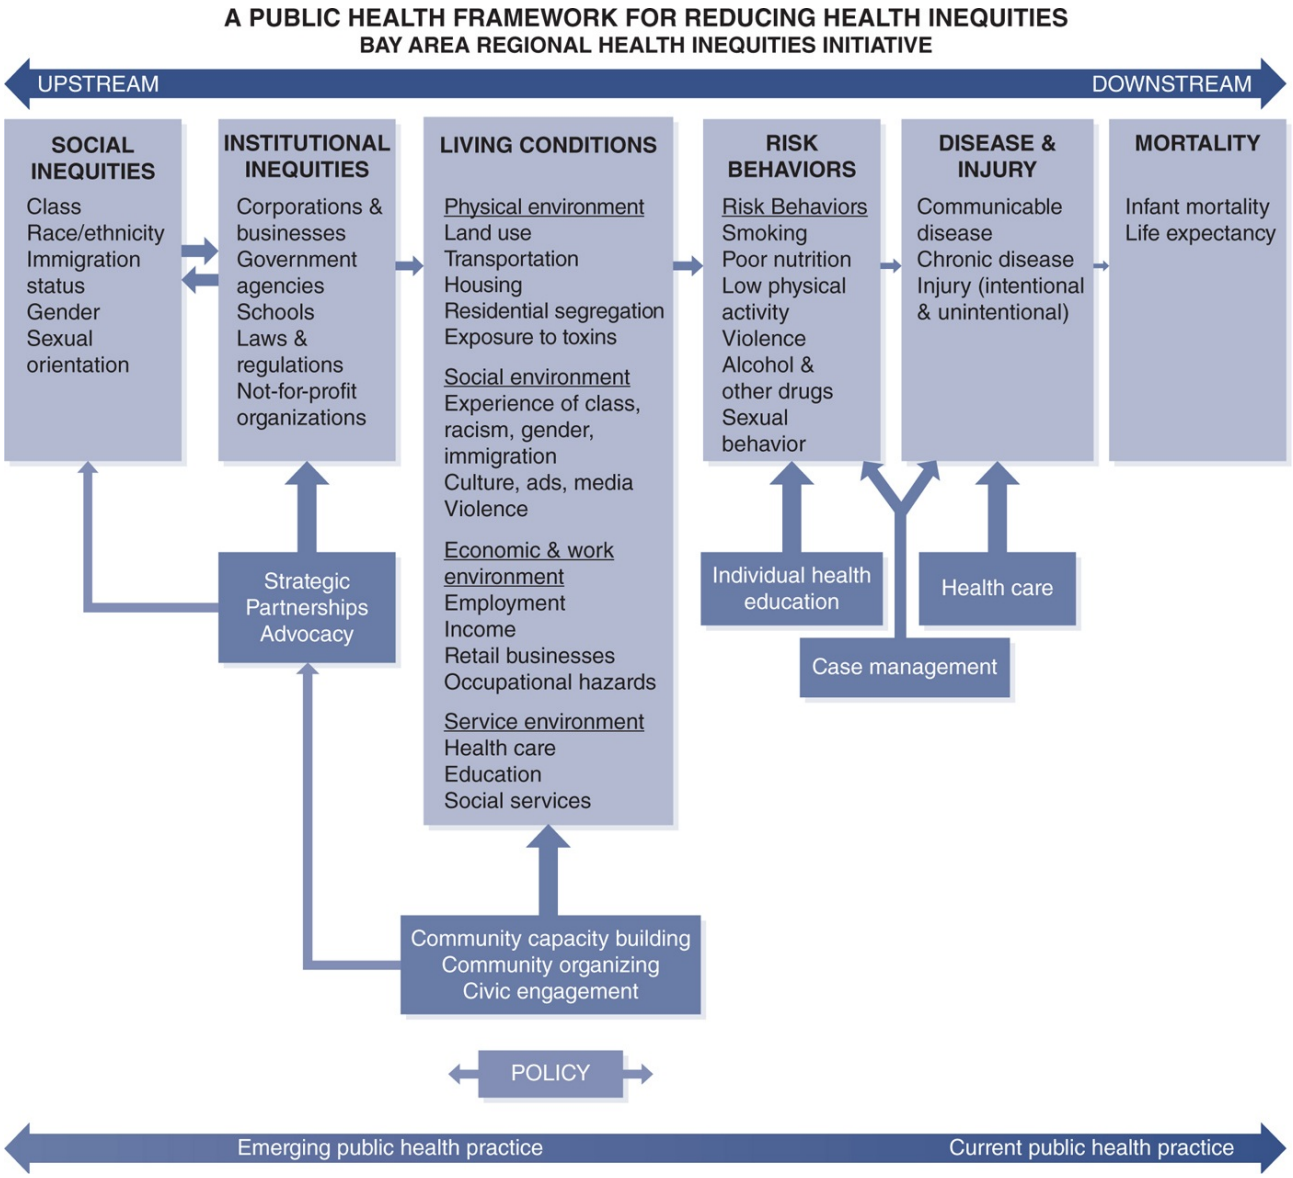

Figure 3-1 Public health framework for reducing health inequities.

Reproduced with permission from Bay Area Regional Health Inequities Initiative. Available at: http://barhii.org/framework/. Accessed January 16, 2018.[16]

Midwives have a long history of recognizing and addressing social determinants of health. Long before the term was coined, midwives worked as general healers within their communities, with their services encompassing a public health and preventive health perspective. For example, grand midwives in the American South, such as Onnie Lee Logan, brought food and social support in addition to clinical care for their clients, who were living in poverty.[17] Frontier midwives, such as Mary Breckinridge, encouraged the building of sanitary toilets and chlorinating infected wells to improve the health of families.[18] Sanba midwives in the American West, such as Toku Tosiko, offered culturally and linguistically competent care to the Japanese immigrant community, serving as cultural brokers as well as healthcare providers.[19]

The commitment to recognize and address social determinants of health continues today, as a

foundational precept of midwifery practice. Contemporary examples include midwives who are involved in maternity care models designed to address race-based health disparities,[20] environmental research and activism addressing high levels of environmental toxins found in breast milk in Mohawk communities,[21] and new models of care such as CenteringPregnancy in which women and families establish social support networks that support optimal health outcomes as they share the journey of pregnancy and parenting.[22,23]

Braveman describes four common mechanisms of action by which SDOH affects health outcomes:[5]

- *Direct, rapid-acting exposures* are specific insults that cause direct, immediate mental and/or physical health consequences for the individual. For example, children raised in substandard housing with chronic exposure to lead in the home or water source can develop long-term cognitive disabilities.
- *Indirect, rapid-acting exposures* are exposures to insults that are immediate but indirectly contribute to adverse mental and/or physical health. For example, the availability of alcohol in a community increases the likelihood of alcohol-related trauma.
- *Indirect impact on health behaviors* comprises exposures to insults that indirectly impact current or future health behaviors. For example, "food deserts"—that is, areas with minimal access to fresh produce and high concentrations of fast-food options—are associated with poor nutrition that, decades later, may result in chronic disease.[24]
- *Complex and long causal pathways* are chronic exposures to social and environmental stressors, including discrimination, that lead to biological "wear and tear." These long-duration causal pathways may take place over a lifetime and/or persist from generation to generation. For example, Geronimus's "*weathering*" theory describes how repeated biological adaptations to chronic stress create physiologic burden (allostatic load) and lead to premature aging and morbidity, with the highest rates found among black women.[25]

Stress, Allostasis, and Epigenetic Mechanisms

The biologic mechanisms by which chronic stress mediates the relationship between SDOH and adverse health outcomes have been the subject of a great deal of research at both the individual and population levels. *Allostasis* refers to the body's dynamic responses to stress that work to maintain homeostasis.[26] When a person experiences chronic stress, the physiologic mediators of allostasis such as cortisol induce adverse effects such as diminished immune response or development of atherosclerosis. This is the mechanism by which chronic stress and high levels of stress adversely affect health through *weathering*.[27] Chronic stress or allostatic load can also induce epigenetic changes. *Epigenetic modifications* refer to DNA methylation, histone modifications, and noncoding RNAs that are the body's response to trauma. Cellular evidence such as shortening of telomere length, which is associated with shortened lifespan, is seen more frequently in persons exposed to chronic stress or discrimination.[28]

Epigenetic changes act as mediators of future adverse health. For example, epigenetic

modifications may explain the biologic manifestations of *historical trauma*, referring to the cumulative emotional and psychological damage that occurs over the lifespan and across generations following massive group experiences.[29] Epigenetics and historical trauma may also be partially responsible for the finding that black women have higher rates of preterm birth and higher rates of infant mortality than do white women with similar demographic characteristics.[30-32] In individuals, epigenetic changes may explain some of the findings that link prenatal or early childhood exposures with adverse health outcomes in adulthood.[27,30-32]

Life-Course Perspective

The response to stressors is highly variable among individuals, so another concept is needed to help midwives understand how these processes affect the health of individuals. The "life-course perspective" has been widely adopted by public health and maternal–child health advocates as a framework for understanding the interplay of SDOH and protective factors on health status.[32] This framework incorporates toxic environmental exposures, nutrition, stress, and health behaviors as environmental influences on biology, including fetal origins of adult disease. Most importantly, the life-course perspective incorporates the protective factors that individuals and communities employ in resistance to environmental risk factors, including resilience, social support, self-esteem, and self-efficacy. The *developmental origins of health and disease* (DOHaD) framework is a rapidly growing body of knowledge that encompasses the theories of allostasis, epigenetics, weathering, and life-course perspective to explore individual and multigenerational effects of prenatal stressors.[26-28,30-33]

Health Disparities

Health disparities are differences in health outcomes and the determinants of those outcomes between groups within a population, as defined by social, demographic, environmental, and geographic attributes.[34] Health disparities occur because unequal access to resources results in worse health outcomes for disenfranchised groups. In essence, health disparities are the downstream effect of social determinants of health. The following sections present an overview of some prominent well-documented health disparities that affect clients of midwifery care. Health disparities are not natural or inevitable, but rather are socially constructed—so they can be eliminated through social change.

Socioeconomic Status

Socioeconomic status (SES) is the term used to describe the social location of an individual, or population, with respect to that person's or population's access to money and resources. Markers frequently used to assess SES include wealth, income, profession, and educational attainment. SES cannot be adequately represented by income level alone, however, because income typically fluctuates significantly over the course of an individual's lifetime. Additionally, SES at specific moments over the life course may have more or less impact; for example, some evidence suggests that childhood SES impacts adult health independent of adult SES.[35]

Socioeconomic status is difficult to quantify because multiple factors influence its effects. For example, abundant evidence shows that the general SES in a neighborhood is correlated with health outcomes independent of individual SES.[36] Low-SES neighborhoods tend to have a cluster of social and politically mediated structural disadvantages that impact both acute and long-term health, such as lack of access to high-quality food sources, increased exposure to environmental toxins, lower-quality education and housing options, and poor access to public transit.[36]

Despite the difficulties inherent in accurately assessing SES, a significant body of evidence indicates that SES is correlated with health, and that this effect is dose-dependent. As a consequence, populations with low SES tend to have poor health outcomes, middle-SES populations tend to have average health outcomes, and high-SES populations tend to have the best health outcomes.[3,36,37]

Racial Disparities

The United States faces a crisis related to the ubiquitous and persistent race-based disparities in health for all persons including maternal–child health. Racial differences in health status and prevalence of illness are not due to genetic differences between racial groups. In fact, there are no specific genetic characteristics that differentiate one "race" from another, and there is just as much genetic diversity within racial groups as there is between them.[38] A person's race does not provide substantive biological information about that individual, nor does it provide an account of the ancestry or culture of the individual. As Dr. Camara Jones, president of the American Public Health Association, has noted, "the variable 'race' is not a biological construct that reflects innate differences, but a social construct that precisely captures the impacts of racism."[39] Nevertheless, racism has resulted in the systematic disenfranchisement of peoples of color within the United States—a factor that is responsible for multiple racial/ethnic disparities. For this reason, race and ethnicity are useful indicators when conducting research about individuals and groups who have borne the brunt of systemic injustice.[40,41]

Racism has traditionally been assumed to operate on three levels: institutionalized, personally mediated, and internalized. In recent years, however, this framework has been expanded to include systemic racism.

- *Institutionalized racism* is the "differential access to the goods, services, and opportunities of society by race."[39] This level of racism is deeply embedded in the structures of our society and "often manifests as inherited disadvantage."[39] It is often invisible and has no identifiable perpetrator. Institutionalized racism shapes an individual's relationships with the social determinants of health, and is the reason that race is associated with socioeconomic status.[39]
- *Personally mediated racism* involves prejudice and discrimination. Prejudice is the "differential assumptions about the abilities, motives, and intentions of others according to their race," whereas discrimination is "differential actions toward others according to their race."[39] This level of racism encompasses conscious discrimination as well as unconscious or implicit bias, and often manifests as disrespect, devaluation, and dehumanization.
- *Internalized racism* is defined as "acceptance by members of the stigmatized races of negative messages about their own abilities and intrinsic worth."[39]
- *Systemic racism* refers to the way racism is embedded in society via policies, structures, and norms (e.g., norms such as white race racial frames) that perpetrate racism.

An overview of race-based disparities in maternal health outcomes, infant health outcomes, and access to and utilization of prenatal care is presented here because these are prominent examples of racial health disparities germane to midwifery practice. However, racial disparities in health outcomes are not limited to maternal–child health.

Racial/Ethnic Disparities in Maternal–Child Health Outcomes

In the United States, black women have a three- to four-fold increased risk of dying of a pregnancy-related cause compared to white women.[42] This racial disparity is even more severe in some specific regions of the country. A study conducted in New York, for example, found black women were 12 times more likely to die from pregnancy-related causes than white women.[43] Although black women do not experience higher rates of preeclampsia, eclampsia, placental abruption, placenta previa, or postpartum hemorrhage compared to white women, they are significantly more likely to die from these complications.[44] Other groups of color are also at increased risk for maternal mortality, with Native Americans/Alaska Natives being 1.5 times more likely to die in childbirth than white women. Maternal mortality is just the tip of the iceberg, though—for every maternal death, there are 100 women who experience severe maternal morbidities.[42]

Similarly, rates of infant mortality demonstrate striking racial disparities. Infants born to Native Americans are 1.5 times more likely to die before their first birthday, and infants born to black parents are 2 times more likely to die in the first year of life. Data suggest that 80% of the black–white disparity in infant mortality is associated with a racial disparity in rates of extremely premature birth.[44] Black and Native Americans are at much greater risk for preterm birth than other racial groups. Racial disparities in preterm birth are especially disturbing because the health impacts for survivors of such births are lifelong effects. Black women are also at increased risk for fetal growth restriction and fetal demise.[44]

Although the etiology of health disparities is complex, multifactorial, and incompletely understood, some of these outcomes can be attributed to social inequities. For example, the higher rates of fetal growth restriction may be due to the fact that black women are at higher risk for having inadequate pregnancy weight gain and experiencing food insecurity in pregnancy, and are more likely to live and work in areas with high levels of environmental pollutants.[44] Most studies have found that Hispanic women are at increased risk for giving birth to infants with neural tube defects. In one study, the spina bifida rate for Hispanic people was 4.18 per 10,000 births, compared to 2.90 and 3.37 per 10,000 births for black and white people, respectively.[44] Hispanics have also been found to have lower rates of folic acid intake —a factor that is associated with an increased risk for neural tube defects.

Native American, Hispanic, and non-Hispanic black women are also at higher risk for starting prenatal care late compared to their white counterparts. In 2014, 11% of Native American women and 10% of black women initiated prenatal care in the third trimester or not at all, compared to only 4% of white women.[45] Insurance status and access to housing, transportation, and child care are all key social factors contributing to the etiology of this disparity.[45] Another likely contributor is perceived discrimination.

Racial and ethnic differences in maternal–child health outcomes are not explained by difference in genetics or “culture,” as studies continue to find that foreign-born individuals have better birth outcomes than U.S.-born persons of the same racial/ethnic groups, despite the fact that foreign-born women tend to start prenatal care later in pregnancy and have lower levels of formal education.[45] Most telling, the significant disparities in infant mortality, low birth weight, and preterm birth are not seen with foreign-born blacks, Asians, Hispanics, and

Filipinos. This phenomenon supports the hypothesis that racial disparities in maternal–child health outcomes are at least partially caused by racism and the inequitable social structures it creates, rather than any innate genetic differences between racial groups.[44-46]

Sexual Orientation and Gender Identity

Formal mechanisms of demographic assessment such as the U.S. Census have been slow to include data on sexual orientation, and still do not collect data on gender identity. Nonetheless, it is clear that a large number of lesbian, gay, bisexual, queer (LGBQ) and transgender and gender-nonconforming (TGNC) individuals live in the United States; a 2016 Gallup poll found approximately 10 million adults in the United States identified as lesbian, gay, bisexual, or transgender, with higher rates observed among people of color.[47] A Williams Institute survey published in 2016 estimated that there are 1.4 million TGNC persons in the United States.[48] LGBQ and TGNC persons are disproportionately affected by poverty.[49] TGNC communities, in particular, report severe poverty, regardless of educational attainment. In general, LGBQ and TGNC people of color are significantly more likely to experience poverty than their white peers.[49] **Table 3-2** defines some common terms used in relation to gender identity.[50-52]

Table 3-2 **Selected Terms Regarding Gender Identity**

Term	Definiton
Agender	A person whose understanding of self is outside of the concept of gender, or does not align with a specific gender identity.
Binary gender construct	A social construct that recognizes only two, mutually exclusive gender identities: male and female. In the United States, gender has historically been understood only through a binary construct.
Cisgender	A person whose gender identity is in alignment with the sex assigned at birth; for example, a person who was assigned female at birth and identifies as a woman.
Gender	A social rather than biological construct, which assigns specific roles, traits, and responsibilities to a person based on the sex assigned at birth. These assigned characteristics are rooted in culture and may vary significantly between cultural groups.
Gender expression	The way in which a person outwardly expresses gender. Gender expression includes mannerisms, style of dress, behavior, and modifiable aspects of physical appearance.
Gender identity	A person's internal understanding of self in regard to gender. Gender identity may or may not be in alignment with one's sex or gender expression.
Gender nonconforming	A person whose gender identity is not limited to solely male or solely female. This umbrella term covers a diverse array of gender identities.
Nonbinary	Similar to "gender nonconforming," this is an umbrella term describing a person whose gender identity is not limited to solely male or solely female.
Sex	A construct that classifies people into separate categories based on their chromosomal makeup and the appearance of their genitals. One's natal sex is the sex that was assigned at the time of birth. Although often thought of as binary, in reality there is a great deal of human variation in regard to sex.
Transgender	A person whose gender identity is not in alignment, in some way, with the sex assigned at birth. Transgender people can have binary or nonbinary gender identities.
Transgender woman	A person who was assigned the male sex at birth and has a female gender identity. Transgender women may or may not pursue medical or surgical interventions to better align their physical appearance with their gender identity.
Transgender man	A person who was assigned the female sex at birth and has a male gender identity. Transgender men may or may not pursue medical or surgical interventions to better align their physical appearance with their gender identity.

Today's healthcare infrastructure and systems are ill prepared to meet the needs of LGBQ and TGNC individuals. Non-inclusive data collection, gendered clinic bathrooms, and assumptions of heterosexuality by providers and staff all contribute to a hostile care environment and decrease safety. Electronic health record (EHR) systems are particularly problematic in their inability to accurately capture key health data such as sexual identity, natal sex, and organ systems present; they also create barriers to respectful care by failing to provide clear systems for documenting preferred names and pronouns.[53] Healthcare assessment and decision making are impaired when the provider does not have access to this information.

Research has demonstrated both explicit and implicit biases against LGBQ and TGNC persons among healthcare providers.[54,55] In large national surveys of TGNC individuals, respondents frequently reported delaying or avoiding needed health care or preventive health services due to fear of discrimination.[49]

There are no published studies that describe LGBQ and TGNC content in midwifery curricula. In a national study of obstetrics and gynecology providers, 80% of respondents received no training on TGNC health during residency; only 35.3% reported that they would be comfortable providing care to transgender men, and 29% reported that they would be comfortable providing care to transgender women.[56] These findings are congruent with data regarding the lack of LGBQ and TGNC clinical content in both medical and nursing education programs in the United States. Lim et al.'s 2015 national survey of baccalaureate nursing school faculty demonstrated significant deficits in these areas: 75% of respondents reported that LGBQ- and TGNC-related content was entirely absent or very limited in their school's curriculum, and few reported adequate knowledge on issues pertinent to this population.[55] Lim et al. found a median of 2.12 hours of nursing curriculum time devoted to classroom teaching on LGBQ and TGNC health. Similarly, Obedin-Maliver et al.'s 2011 survey of 176 U.S. medical schools found a median of 2.0 clinical hours related to LGBQ and TGNC health in allopathic training programs, and 0 hours in osteopathic training programs.[55,57]

LGBQ and TGNC Health Disparities

As with many marginalized communities, research on LGBQ and TGNC health is lacking in scope, quantity, and quality, limiting our understanding of the disease burden and health disparities within this population. While limited, the existing data do demonstrate that LGBQ and TGNC individuals experience disparities in both physical and mental health, including those related to depression, anxiety, smoking, alcohol use, and substance abuse. Rates of suicide are higher among LGBQ and TGNC youth as well as among TGNC individuals of all ages compared to their heterosexual peers.[58] Suicidality is highest among those who have experienced social insults such as family rejection, and for TGNC people of color. Available

data also suggest that LGBQ and TGNC persons are at risk of transmission of all sexually transmitted infections (STIs) including human papillomavirus (HPV) and human immunodeficiency virus (HIV), although this risk often goes unrecognized by healthcare providers who treat LBQ women and TGNC individuals.

Metabolic and Cardiovascular Health

Research has consistently demonstrated that LBQ women are more likely to be overweight or obese than their heterosexual peers, with disparities in weight presenting as early as adolescence.[59-61] The clinical significance of this finding, however, is less clear. Systematic reviews of existing data have failed to find evidence of increased rates of obesity-related morbidity such as diabetes, hypertensive disorders, or lipid disorders among LBQ women.[59,62] Despite significant differences in weight status, research has also failed to show a difference in physical activity levels and healthfulness of diet in LBQ versus cisgender heterosexual women.[60] Additionally, limited research has suggested that many overweight or obese LBQ women are metabolically healthy. Similarly, research has revealed greater cardiovascular risk factors in adult LBQ women but has not clearly demonstrated an increase in actual cardiovascular morbidity and mortality.[59,61-63] Data on weight status and metabolic health among TGNC individuals are sparse.

Sexual Health

Misinformation about transmission of STIs and vaginal infections between LBQ women and TGNC individuals is common among both providers and patients. This misunderstanding has contributed to a paucity of research about to STI rates and STI prevention strategies in LBQ women. The data that are available demonstrate that LBQ and TGNC people are at risk of transmission of all STIs including chlamydia, HPV, and HIV.[49,64-69] Bacterial vaginosis (BV) is common in LBQ women,[67] but data are not available on rates of BV in TGNC natal females.

Although the risk of direct female-to-female sexual transmission of HIV is low, HIV infection risk in LBQ women must be assessed in the full context of the individual's life risk factors, which may include sharing of needles during intravenous drug use, sex with natal males, and perceptions of invulnerability. For providers, it is important to recognize that identity and behavior do not always match; actual behaviors must be assessed by taking a comprehensive sexual history.

While data are still scant, more information is available on the incidence of HIV in TGNC persons. Data from the National HIV Surveillance System reveal that a total of 2351 TGNC people were newly diagnosed with HIV between 2009 and 2014; 84% were transgender women, 15.4% were transgender men, and 0.7% were people with nonbinary or other gender identities.[69] The majority of these diagnoses were in African American TGNC individuals.

It is likely that HIV and STI rates in LBQ women and TGNC people are underestimated due to deficiencies in reporting systems, bias in research design, provider discomfort with completing appropriate sexual health histories, and lack of provider knowledge about disease transmission risk.[70] For example, few studies capturing data on sexual health in transgender

men report the natal sex of participants' sexual partners, likely under the assumption that transgender men partner only with natal females.[71] Without this information, it is difficult to assess magnitude of risk; this is particularly concerning given that risky sexual behaviors in transgender men are associated with partnering with natal males.[71]

Violence Against LGBQ and TGNC People

Violence against LGBQ and TGNC persons accounts for a significant proportion of hate-based violence in the United States, and is most common against persons of color.[72] Transgender women of color bear the highest burden of lethal anti-LGBQ and TGNC hate violence in the United States. In November 2017, the Human Rights Campaign and the Trans People of Color Coalition released a report confirming that a total of 25 murders of TGNC people had been reported in the United States that year; another 3 TGNC people were murdered by the end of the year.[73] The number of reported LGBQ and TGNC hate crimes is lower than the true incidence due to both victim hesitance to report these crimes and failure of the law enforcement system to properly investigate and classify these crimes.[74]

Violence against LBQ and TGNC persons, including hate-based violence, often occurs at the hands of school peers, family members, and intimate partners. In a 2014–2015 national survey of 10,528 gay, LBQ, and TGNC youth between the ages of 13 and 21 years, experiences of discrimination and fear were common. In this cohort, 58% reported that they felt unsafe while at school due to their sexual orientation; 27% reported experiencing physical harassment and 13% reported experiencing physical assault due to their sexual orientation.[75] Among students who were subjected to discrimination due to their gender identity, 43% reported feeling unsafe, 20% reported physical harassment, and 9% reported physical assault.[76]

Gender-Based Violence

The term *gender-based violence* is used to describe the violence that occurs as a result of gender role expectations and inequality in the access to power, money, and resources by different genders.[77] This term is broad enough to capture shared root causes in a range of expressions of violence and dominance. In this section, four forms of gender-based violence that have implications for clinical midwifery care are reviewed: (1) violence against LGBQ and TGNC persons, (2) intimate-partner violence (IPV), (3) reproductive coercion, and (4) sexual coercion.

In the United States, 1 in 3 cisgender women and 1 in 6 cisgender men will experience sexual violence in their lifetime. Midwives provide sexual and reproductive health care to individuals of all ages and particularly during times when the psychological effects of gender-based violence may be triggered, such as pregnancy, labor, and birth. The topic of how gender-based violence affects health and the provision of *trauma-informed care* is of particular importance in midwifery. Midwives must be prepared to offer harm-reducing strategies and ready to provide referrals as needed. Harm-reducing strategies include discrete discussions regarding contraceptive options and establishing a safety plan.

Family and intimate-partner violence are also common experiences for LGBQ and TGNC youth and adults. In the 2015 U.S Trans Survey, 10% of respondents reported violence perpetrated by a family member due to their gender identity (at any age), and 26% had been excommunicated by an immediate family member due to their gender identity.[49] Some data suggest that rates of IPV among LGBQ and TGNC adults are approximately the same as those among heterosexual couples;[78] other data suggest higher lifetime rates, including for severe physical IPV.[49,79] Among LBQ women, bisexual women experience the highest rates of IPV and are also more likely than their lesbian and heterosexual peers to experience sexual violence.[79]

Intimate-Partner Violence

Intimate-partner violence is a pattern of assaultive and coercive behaviors that includes inflicted physical injury, psychological abuse, sexual assault, progressive social isolation, stalking, deprivation, intimidation, and threats. IPV is perpetrated by someone who is, was, or wishes to be involved in an intimate or dating relationship, and these behaviors are aimed at establishing control over one partner by the other.[80] IPV can affect any person, regardless of gender, sexual orientation, race, physical ability, or SES. Although cisgender men and women both experience IPV, significantly more cisgender women than men report needing medical care and experiencing longer-term consequences such as ongoing fear and post-traumatic stress disorder symptoms.

Intimate-partner violence may occur for the first time or worsen during pregnancy.[82,83] Persons who are pregnant or in the first year postpartum are at increased risk for homicide, with the majority of these crimes occurring secondary to IPV.[80,82,83] Beyond physical outcomes of IPV, victims are at increased risk for a range of other negative health-related sequelae, including STIs, pelvic inflammatory disease, and unintended pregnancy. Persons who have experienced IPV also have higher rates of physiological disorders and mental health conditions

such as chronic pain, neurologic disorders, gastrointestinal disorders, migraine headaches, depression, post-traumatic stress disorder, anxiety disorders, substance abuse, and suicidal behavior. Among women who are pregnant, IPV is associated with an increased risk for preterm birth and low birth weight.[84] Pregnant women who are hospitalized following assault have higher rates of multiple adverse outcomes, including placental abruption, uterine rupture, fetal demise, and preterm birth.[85]

Screening and support for women who have experienced IPV is reviewed in several chapters in this text. Many individuals may not choose to disclose current or past gender-based violence. However, routine screening can provide an opportunity to offer information about healthy relationships, safety plans, and nonjudgmental support.

For clients who disclose current or past experience with gender-based violence, further assessment of risks and information about safety plans and resources can be offered. It is also important to assess their current safety. All clients, including those who do not disclose current or past IPV, should be provided with safety information about violence. Evidence shows that receipt of safety information reduces violence and increases safety for recipients, even for those who did not disclose an unsafe relationship during the healthcare provider's assessment. Resources for IPV screening and safety information are listed at the end of this chapter.

Reproductive and Sexual Coercion

Reproductive coercion describes "behaviors aimed to maintain power and control in a relationship related to reproductive health by someone who is, was, or wishes to be involved in an intimate or dating relationship with an adult or adolescent."[86] Reproductive coercion includes tampering with a person's birth control in an explicit attempt to make the person become pregnant. It also includes coercive, threatening, or violent behavior intended to make a person end a pregnancy the individual does not want to end or continue a pregnancy the individual does not want to continue. People who are the victims of IPV are at higher risk for reproductive coercion.[86,87]

Sexual coercion "happens within the context of a relationship" and includes a range of behaviors that are used to coerce a person to have sex but do not rely on physical force. Examples of sexual coercion include forcing or repeatedly pressuring a partner to have sex, refusing to use a condom and nonconsensual removal of a condom during sex, intentionally exposing a partner to an STI, or threatening or harming a partner when notified about a positive STI test.

Trauma-Informed Care

Healthcare examinations can trigger fear, trauma, or post-traumatic stress symptoms in persons who have a history of sexual abuse, prior experience with insensitive providers, or prior experience of painful care. Furthermore, the United States has a history of obstetric violence and reproductive coercion that disproportionately affects women of color, a fact that contributes to historical trauma.[88] Approximately one-third of cisgender females have experienced sexual abuse. Because pelvic examinations are commonly recommended in

midwifery practice, trauma-informed care is another technique of import that all midwives can incorporate into their clinical practice.[89] Trauma-informed care includes multiple strategies that allow the client to maintain control, including careful attention to respectful language and obtaining permission, shared decision making, self-collection of vaginal samples, offering to let the client insert a vaginal speculum, and avoiding use of stirrups.

Techniques and Tools to Address Health Disparities in Midwifery Practice

The combined effects of social determinants of health, healthcare provider bias, and discrimination form a potent force that creates and perpetrates health disparities. The population served by the midwifery profession is more racially and ethnically diverse than is the population as a whole,[90] which makes health disparities a topic of prime importance in midwifery practice. This section presents an introductory overview of ways midwives can provide care that incorporates knowledge about social determinants of health, healthcare provider bias, and the effects of discrimination.

Cultural Competency, Cultural Humility, and Structural Competency

Culture is an integrated pattern of human behavior that includes the sum of actions, behaviors, language, thoughts, communications, customs, beliefs, values, and institutions that differentiate one group of people from another group. Culture is dynamic, not static. Moreover, culture is necessarily made up of both visible and invisible components. For example, actions and behaviors are visible components of culture, while the ideas, values, and attitudes that support action and behavior are not visible. Failure to recognize the core aspects of culture that are not visible is a major impediment in any effort to meet an individual's needs.

As the U.S. population has become more diverse, the need to provide *culturally and linguistically appropriate services (CLAS)* has become increasingly necessary in healthcare delivery. CLAS standards for healthcare services were initially developed in 2000 by the U.S. Department of Health and Human Services Office of Minority Health[91]; these standards provide a blueprint for implementing culturally and linguistically appropriate services. In 2003, the publication of *Unequal Treatment*: *Confronting Racial and Ethnic Disparities in Health Care* by the Institute of Medicine further documented the need for CLAS in healthcare services.[14] Subsequently, healthcare organizations have established requirements for cultural competency training.

The *cultural competency* framework requires providers and healthcare systems to "understand the importance of social and cultural influences on patients' health beliefs and behaviors and consider how these factors interact at multiple levels of the health care delivery system." Key to achieving cultural competence is the expansion of cultural knowledge and subsequent adaptation to cultural differences.[92]

Despite being a popular framework that has been widely promoted, cultural competence training has had only modest success. Notably, these programs improve knowledge and attitudes among providers, but have only a limited effect on patient outcomes.[93] In fact, the cultural competency framework may reinforce stereotypes rather than expand awareness and understanding. For example, "culture" is often conflated with racial or ethnic identity, thereby reinforcing racial stereotypes. Perhaps one of the most important critiques of the cultural competency framework is that it maintains the normative perspective of the dominant social categories, which suggests that the patient is responsible for culturally assimilating so as to

improve health.[94]

Nonetheless, there is obvious inherent value in understanding the cultural beliefs and norms that influence a person's perceptions and behaviors. This understanding can be better achieved when approached from a *cultural humility* perspective: "a commitment and active engagement in a lifelong learning process that individuals enter into on an ongoing basis with patients, communities, colleagues and themselves."[95] In addition to promoting ongoing attentiveness, respect, and openness toward others' perspectives and experiences, cultural humility focuses on ongoing critical self-reflection of one's individual culture(s), acknowledging personal beliefs, values, and experiences. This includes critical self-reflection on the culture of the midwifery profession and the healthcare system. Cultural humility encourages consideration of the power dynamics in the patient–provider relationship so that it can be reframed to a partnership and opportunity for advocacy.

Each healthcare interaction occurs in the context of three cultures: (1) the midwife's lived experience, (2) the experiences of the person seeking care, and (3) the culture of the healthcare system itself. Cultural norms and values shape a midwife's approach to care, and cultural forces shape the healthcare system as a whole. Thus, helping a person attain optimal health requires an awareness and assessment of the effects of all three cultures.

In describing any culture or cultural practice, it is important to note that within-group differences are likely to be as great as across-group differences. Wide variations in attitudes, beliefs, and behaviors exist among individuals. To assume that people who share a common culture and language are alike in all ways is to make a dangerous mistake. In addition, just as individuals may have multiple social identities, they may identify with multiple cultures simultaneously and over the course of their lifetimes.

Structural Competency

Structural competency extends the concept of cultural humility; it is the trained ability to understand how symptoms, attitudes, or diseases represent downstream implications of a wide variety of upstream structural systems. Structural competency is defined by the development of five core skills: (1) development of an extra-clinical language of structure, (2) rearticulation of "cultural" presentations in structural terms, (3) imagining of structural interventions, (4) development of structural humility, and (5) recognition of the structures that shape clinical interactions.[96]

Developing an extra-clinical language of structure requires an awareness of how social structures affect the health of communities. Rearticulating "cultural" presentations in structural terms invites the midwife to recognize and describe the structural causes of "cultural," "behavioral," or "lifestyle" risk factors—for example, recognizing and exploring the impact of food deserts and lack of access to safe recreational spaces on the food- and exercise-related habits of clients from low-SES neighborhoods. Imagining structural interventions encourages the midwife to conceive of and participate in developing interventions that address barriers to optimal health. Developing *structural humility* ensures that the midwife recognizes the need to continue learning. This is a lifelong commitment to learning and growing. Taken together, these four skills sets help the midwife recognize the structures that shape clinical interactions,

including the various economic, social, and political forces that affect the person, as well as the contributions made by the power and privilege dynamic between the patient and the clinician in the clinical encounter.

Interventions That Address Social Determinants of Health

Interventions that improve health disparities often involve multidisciplinary partnerships between healthcare providers and community organizations.[97-100] A thorough review of all interventions that may potentially decrease health disparities is beyond the scope of this text, but the reader is referred to the Resources section at the end of this chapter and recent reviews for more information.[97-100] Among the interventions that show promise as a means of improving health disparities in maternity care are screening for social determinants of health at initiation of care, bundling of prenatal care with other services that address social determinants known to affect the population, CenteringPregnancy group prenatal care, home visiting programs using community health workers and nurses, and accountable care organizations.[45] One intervention that has not yet been given significant attention is increasing diversity among the healthcare workforce.

Racial and Ethnic Disparities Effects on the Midwifery Workforce

A growing body of literature demonstrates that racial diversity in the healthcare workforce increases access to care, boosts adherence relative to treatments, and improves the quality of patient–provider interactions for people of color.[101,102] Midwives of color serving clients of similar backgrounds are uniquely positioned to understand the social, economic, and political forces that affect their patients. Cultural and *values concordance* facilitates communication and the provision of high-quality care.[101,102] Although racially diversifying the healthcare workforce is certainly an important intervention that can reduce racial disparities in health, currently 98% of nurse-midwifery practitioners in the United States identify as white.[103] Racism also limits access to midwifery education. Studies of midwives of color have found that institutional and interpersonal racism is pervasive in midwifery education programs, clinical settings, and professional organizations, and this racism poses a barrier to persons of color joining the midwifery profession.[104]

How did midwifery evolve into a predominantly white profession? Also, how does the profession's lack of racial diversity impact a midwife's ability to care for persons from diverse populations? A brief history of midwifery in three different communities of color offers a glimpse into the work of midwives in these communities and highlights the care they have provided. These stories exemplify the value of social/cultural concordant care and show how midwives who are part of the communities that they serve can bridge the gap between cultures to better meet women's needs. These stories also document how racism has contributed to the elimination of midwives of color, thereby producing the lack of workforce diversity now apparent.

New Mexico's Curandera-Parteras

—Felina M. Ortiz

Historically, traditional midwives, especially in communities of color, provided much of the maternity care. Most were elders in their community and were apprenticed for many years by their ancestors.[105] The midwives shared the communities' language and culture. As allopathic medicine was increasingly adopted and traditional midwifery became less valued in many parts of the United States, New Mexico was one of the few states that worked with the traditional Hispanic midwives, known as *curandera-parteras*, instead of against them. Officials of the New Mexico Department of Health recognized the challenge of providing obstetric care in the rural communities and the need for the *curandera-parteras*. In 1936, New Mexico's public health service bridged traditional health and modern medical care with a formal midwifery consultant program.[105] This program offered educational support and supplies to the *curandera-parteras*, while they in turn provided much needed obstetric care in hard-to-reach communities and completed the paperwork that improved New Mexico's vital statistics database. This partnership was one of the many elements that contributed to New Mexico being the state with the highest percentage of midwife-attended births in the nation to this day, almost a century after the program began.

In 1979, New Mexico introduced regulations that required all practicing *curandera-parteras* to obtain formal education and pass the licensing examination in English. These regulations worked toward the elimination of these practitioners, as many of them were not English literate.[105] This system of oppression and the loss of these practitioners disrupted an established system of maternal–child health care and is a potent illustration of institutional and systemic racism.

Grand Midwives of African Ancestry

—Patricia O. Loftman, Betty Jane Watts Carrington, Heather Clarke, Carolyn Curtis, and Karline Wilson-Mitchell

The origin of the traditional grand midwife began in Africa and was transplanted to the Americas through the trans-Atlantic slave trade in the 1600s. The grand midwives brought their knowledge, skills, and cultural traditions of childbirth that had been transmitted throughout generations via observation, apprentice training, personal experience, and oral tradition. During the period of enslavement, these midwives attended births, provided many other healthcare services, and were the foundation of the healthcare system for enslaved people on plantations. The midwife was respected and revered not just as an elder, but as a central and integral figure in the home and community. Grand midwives lived in the community, knew families intimately, and acted as an advocate and a source of comfort and support as they carried on the tradition of serving families through generations.

Onnie Lee Logan (1910–1995), who delivered hundreds of babies between 1931 and 1984, seemed to know every secret, herb, folk remedy, and "God-given motherwit" required to give birth in a poor community. She performed a role that many midwives filled, meeting needs holistically, whether catching a baby or providing food to a poor family.[17] Margaret Charles Smith (1906–2004) worked as a midwife in the days of Jim Crow laws that enforced racial segregation in the Southern United States. Ms. Smith described how she had to enter through the side or back door to attend white mothers. She also described how home births provided

the opportunity for the midwife to "stay with the woman as long as she needed," in contrast to the lonely hospital environment. She viewed her role as providing support, knowledge, and advocacy in her community.[106]

Discriminatory regulations developed by campaigning physicians and public health departments successfully eliminated grand midwives from practice in the 1930s and 1940s using methods that would today be described as structural and systemic racism. Physician representatives created financial incentives associated with providing maternity care for their peers and promoted propaganda that described African American midwives as "illiterate, uneducated, dirty, and dangerous." High rates of maternal and infant mortality were blamed on the practices of the grand midwives rather than on unequal access to public resources. Grand midwives were subsequently required to register with local health departments to obtain a practice permit and were required to attend classes at state training institutes.[107] The campaign was effective—but as more births took place in the hospital with physician attendants, maternal and infant mortality sharply increased, with many deaths due to infectious diseases and complications from unnecessary medical interventions.

The first formal educational program for African American midwives, Tuskegee School of Nurse-Midwifery, opened in 1941 but was in existence for only 6 years. Tuskegee graduated 31 African American nurse-midwives who provided general health care, became liaisons and resources between the community and local health departments, contributed to reductions in maternal and infant morbidity and mortality rates, and educated future generations of African American midwives. Two of the most notable Tuskegee graduates were Maude Callen (1898–1990) and Constance Manning Derrell. Mrs. Callen served her community in South Carolina for more than 50 years, increasing the visibility of nurse-midwives. Traditional grand midwives laid the foundation and their legacy provides inspiration to contemporary midwives of color. Their work can be seen as a blueprint for the provision of high-quality, client-centered care

Indigenous Midwives and the Indian Health Service

—Susan Stemmler and Nicolle L. Gonzales

The history of Indigenous midwifery in the United States is a tapestry of anthologies, held in the hearts of birth knowledge keepers across Turtle Island (North America). Much of that knowledge was passed down through stories from grandmothers to granddaughters, and from medicine women to their apprentices. During the early twentieth century, while traditional grand midwives were serving African American and poor women in the South and *curandera-parteras* were attending the births of Latina women in New Mexico, indigenous traditional midwives were attending the births of American Indian and Alaska Native women in their homes.

Historically, indigenous traditional midwives were responsible for the births of American Indian and Alaska Native people. Over the centuries, American Indian and Alaska Native communities were transformed by U.S. governmental policies and predatory assimilation practices that forever changed the lives of American Indian people.

The relationship between tribal governments and the federal government is founded in the

U.S. Constitution, which recognizes that federally recognized Indian tribes are sovereign nations with certain inherent rights. This distinguishes American Indians and American Natives from all other ethnic groups in the United States. Many of the treaties recognize government-supplied health care as payment for the U.S. government taking Indian lands. Today the Indian Health Services (IHS), which is housed in the U.S. Department of Health and Human Services, is the principal provider of health care and health advocacy for the 567 federally recognized indigenous tribes in the United States.

Traditional midwives were not included or utilized as part of the IHS mission; however, traditional knowledge keepers and birth attendants continued to share ceremonial teachings with their communities outside the formal profession of nurse-midwifery. Today nurse-midwives working for IHS attend more than 75% of all births, although nearly all midwives employed by IHS are not of American Indian or American Native descent. Nonetheless, Native American nurse-midwives have worked to bridge indigenous customs with hospital care.[108] For example, Ursula Knoki-Wilson, who began practice at the Chinle Comprehensive Health Center hospital in 1977, received the 2017 W. J. Haffner American Indian/American Native Women's Health Award for her years of service to advancing women's health care and cultural awareness for American Indian and Alaska Native women.

There is currently a movement to reclaim indigenous birth knowledge within tribal communities. The definition and scope of indigenous midwifery are evolving, and many Indigenous women are seeking this knowledge through their community healers and midwives. Many indigenous midwives choose to work outside the healthcare systems because the dominant culture in these sites does not support the ceremonial wellness that is important to members of these communities. The history of indigenous midwifery is still being written and the future of indigenous midwifery is still being molded, while interweaving evidence-based practice and traditional indigenous practice.

Conclusion

This chapter presents a broad overview but only a brief introduction to a few of the critical factors that affect an individual's health. Space limitations precluded the inclusion of important topics such as health literacy and health numeracy, which are essential for understanding healthcare information. In addition, several critical health disparities were not addressed in this chapter, including those secondary to lack of access to healthcare services, a serious problem for many who live in rural settings. Similarly, information about the needs of populations such as religious minorities, immigrants, persons with disabilities, and persons exposed to trauma or adverse childhood experiences was not included. The content presented here can be used as a framework for a way to approach clients and what needs to be understood to care for clients who come from many different backgrounds, histories, and cultures—midwifery is a lifelong learning process.

Other chapters in this text address the clinical knowledge needed to offer specific healthcare services. Nevertheless, clinical expertise can be effective only when the topics presented in this chapter are addressed. Each healthcare encounter between a midwife and a client occurs within a social and cultural milieu that can either perpetrate health disparities or mitigate them. Addressing social determinants of health, avoiding healthcare provider bias, and providing care that meets the needs of the individual is essential every time, with every person.

Maternal and infant mortality statistics are used extensively to document trends in health status and the results of therapeutic interventions at the population level. These statistics are also used extensively in healthcare research and by governments and institutions worldwide when deciding where to dedicate resources. In the United States, data on births, deaths, and fetal deaths are collected by each state or jurisdiction and reported as vital statistics to the National Center for Health Statistics. The National Vital Statistics System is a partnership between the federal government, 50 states, 2 cities (Washington, DC, and New York City), and 5 territories (Puerto Rico, the Virgin Islands, Guam, American Samoa, and the Commonwealth of the Northern Mariana Islands). The states and territories have the legal responsibility to register vital events. Although most jurisdictions use the standard U.S. forms for birth and death data, some variations are apparent between states and territories with regard to which data are collected. Thus, the data collected are not completely uniform across all jurisdictions.

Health statistics are an accepted measure of the effectiveness of a healthcare system and widely used as indicators of a nation's health. Mortality statistics also illustrate how pregnant women and newborns fare both internationally and within the United States. There are striking differences in mortality and morbidity statistics between the United States, other developed nations, and low-resource nations. Within the United States, there are notable racial and ethnic disparities in maternal and infant health outcomes. This appendix briefly reviews definitions of health-related statistics and how they are used. Definitions of key reproductive statistics are presented in **Table 3A-1**.[1-3] The most recent infant mortality, fetal death, and pregnancy-related mortality ratios are presented in **Table 3A-2**[3-5] and **Figure 3A-1**.[6]

Table 3A-1	Selected Maternal/Child Health Indices

Term	Definition and Explanations
Fetal death rate (see Stillbirth)	Spontaneous death of the fetus occurs prior to birth, irrespective of the duration of the pregnancy. Fetal death is indicated by no signs of life after birth (e.g., heartbeats, umbilical cord pulsations, breathing, or voluntary muscle movement). The fetal death rate is the number of fetal deaths ≥ 20 weeks' gestation that occur during a year divided by the sum of live births plus fetal deaths during the same year, and expressed per 1000 live births plus fetal deaths.
Infant mortality rate (IMR)	Number of infants dying before reaching 1 year of life per 1000 live births in a given year.
Lifetime risk of maternal death or pregnancy-related death	Risk of an individual woman dying from pregnancy or childbirth during her life; calculated by multiplying the maternal mortality rate by 30, or the number of years of exposure to pregnancy between ages 15 and 44. Calculations are based on maternal mortality and fertility rates in the country. This method recognizes that women of high fertility or women lacking in universal access to effective family planning have an extremely high risk of dying as a result of pregnancy or childbirth, as they are repeatedly exposed to the risk of pregnancy.
Live birth	Complete expulsion or extraction of a product of human conception from a woman, irrespective of the duration of pregnancy. The newborn shows any evidence of life (ie, heartbeats, umbilical cord pulsations, breathing, or voluntary muscle movement), regardless of whether the umbilical cord has been cut or the placenta is attached. Heartbeats are distinguished from transient cardiac contractions and breathing is distinguished from fleeting respiratory efforts or gasps.
Maternal mortality rate	An estimate of the number of deaths during pregnancy or within 42 days after completion of the pregnancy, per 100,000 women of reproductive age in a given year. This rate is difficult to obtain and often not used in low-resource countries, since births are more easily measured than the number of women of reproductive age.
Maternal mortality ratio	An estimate of the number of deaths during pregnancy within 42 days after completion of the pregnancy, for every 100,000 live births. This ratio is the method most commonly used to express trends within a country and to make international comparisons. Note: The maternal mortality *ratio* differs from the maternal mortality *rate* in that the denominator is births and not women of reproductive age. The rate is more difficult to measure, especially in countries with less sophisticated data gathering.
Neonatal morality rate	The number of deaths of newborns in the first 28 days of life per 1000 live births.
Neonatal death rate (early versus late)	Early neonatal deaths are the number of neonatal deaths that occur before the first 7 days from birth. Late neonatal deaths are the number of neonatal deaths that occur between 7 and 27 days of age.
Perinatal mortality rate[a] (PMR)	The sum of fetal deaths (more than 20 weeks' gestation) plus early neonatal deaths (within the first 28 days after birth) during a year divided by the sum of live births plus fetal deaths during that year. Expressed per 1000 live births plus fetal deaths.
Pregnancy-associated death	Death of a person occurring during or within 1 year of pregnancy but not causally related to pregnancy. This definition contrasts with that of "not pregnancy-associated death"—that is, death of a person with a uterus who has never been pregnant or occurring more than 1year after the end of pregnancy. Reported as the pregnancy-related mortality ratio: pregnancy-related deaths per 100,000 live births.
Pregnancy-related death	Death of a person while pregnant or within 1 year of the end of a pregnancy—regardless of the outcome, duration, or site of the pregnancy—from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes. This includes a pregnancy complication, a chain of events initiated by pregnancy, or the aggravation of an unrelated condition by the physiologic effects of pregnancy.

Stillbirth	Fetal death that occurs ≥ 20 weeks' gestation

[a] There are several definitions of perinatal death rate in use today, including neonatal deaths within 7 days or within 28 days after birth; others use fetal deaths occurring with a gestation of more than 28 weeks.

Infant Mortality

In 2014, the overall infant mortality rate (IMR) in the United States was 6 infant deaths per 1000 live births.[4] However, the IMR varies by geographic location and race/ethnicity and is highest among non-Hispanic blacks (Table 3A-2).[3-5,7] The most common causes of infant death are congenital anomalies, preterm birth or low birth weight, maternal complications of pregnancy, sudden infant death syndrome (SIDS), and unintentional injuries.

The IMR has historically been used as an indicator of the health of a population because the health of infants in the first year of life is heavily dependent on factors such as maternal health, quality of health care, socioeconomic conditions (e.g., nutrition, education, wealth), and public health practices (e.g., sanitation, preventive health services).[8] Despite spending larger amounts of money on healthcare services than many other countries, the United States ranks 26th among developed nations, with an IMR that is approximately twice as high as most other developed nations.

The reasons that the IMR in the United States remains high despite higher levels of healthcare spending are complex and not fully understood. International comparisons have found that the higher IMR can be largely attributed to increased rates of preterm birth and higher death rates in infants born after 37 weeks' gestation.[8]

The most modifiable etiology is likely preterm birth.[5] Many studies have explored strategies designed to decrease the risk of preterm birth, including investigation of environmental

epigenetics, suggesting that improving social determinants of health can directly affect perinatal outcomes.[9] Methods for lowering the rate of preterm birth include interventions such as increasing breastfeeding rates, offering more parental support and education, and improving access to healthcare services.

Fetal Death and Stillbirth

States have different reporting requirements for fetal death. Most report fetal deaths that are 20 weeks' gestation or greater and/or 350 grams or greater birth weight, and use 20 weeks' gestation as the gestational age threshold for distinguishing a stillbirth from the product of a miscarriage. A few states report all pregnancy losses as a fetal death regardless of the period of gestation. The fetal death rate in the United States is approximately the same as the IMR, at 5.96 fetal deaths after 20 weeks' gestation per 1000 live births and fetal deaths combined (denominator). The incidence varies by race/ethnicity and is highest in non-Hispanic blacks.

Maternal Mortality

Maternal deaths are evaluated by three different systems in the United States.[10] The National Vital Statistics System reports the maternal mortality rate and ratio based on death certificates using the World Health Organization's International Classification of Disease codes. These statistics do not generate detailed data about the proximate cause of death. The Pregnancy Mortality Surveillance System within the Centers for Disease Control and Prevention (CDC) monitors pregnancy-related and pregnancy-associated deaths via a more complex analysis of death certificates, birth certificates, and pregnancy data that are recorded on both. These statistics generate more detailed data about the causes of death. The third source of information comes from maternal mortality review committees that analyze pregnancy-related deaths in more detail at the local level.

Maternal mortality is much less common than infant or fetal death and is reported as a number per 100,000 live births. A single woman dying in childbirth is a tragedy; an increase in the number of women dying is a societal catastrophe and national embarrassment. Despite advances in standard of living and healthcare technology, the number of women who die from a pregnancy-related cause has increased in the United States from 7.2 deaths per 100,000 live births in 1987 to a high of 17.3 deaths per 100,000 live births in 2013.[3] The maternal mortality rate in non-Hispanic black women is three times higher than that in non-Hispanic white women (40.2 versus 14.1 maternal deaths per 100,000 live births), which is one of the most striking perinatal health disparities in the United States today.[11] Today the United States ranks 60th in the world, with a maternal mortality rate that is higher than that of all other developed nations.[12] It is estimated that approximately 50% of the U.S. maternal deaths are preventable.[13]

Historically, the most common causes of maternal mortality were hemorrhage, infection, hypertension, and anesthesia complications. As the prepregnancy health status of childbearing women has changed over time, so have the causes of mortality and morbidity. The most common direct causes of pregnancy-related death during 2011–2013 are listed in **Table 3A-3**.[3]

Receiving care at an appropriate site may ameliorate risks for an individual, but problems of poverty, access, and insurance can result in women not obtaining the care needed. Specific factors that are associated with an increased maternal mortality ratio include four or fewer prenatal visits, unintended births, cesarean births, unmarried status, and percentage of black women giving birth within a state.[11] The last factor illustrates a continuing challenge associated with racial and ethnic health disparities in the United States.

Table 3A-3	Leading Causes of Maternal Death in the United States, 2011–2013
Cause	**Percentage of Pregnancy-Related Deaths**
Cardiovascular diseases	15.5%
Noncardiovascular diseases (includes drug overdose)	14.5%
Infection or sepsis	12.7%
Hemorrhage	11.4%
Cardiomyopathy	11.0%
Thrombotic pulmonary embolism	9.2%
Hypertensive disorders of pregnancy	7.4%
Cerebrovascular accidents	6.6%
Amniotic fluid embolism	5.5%
Anesthesia complications	0.1%

Based on Centers for Disease Control and Prevention. Pregnancy Mortality Surveillance System. November 9, 2017. Available at: https://www.cdc.gov/reproductivehealth/maternalinfanthealth/pmss.html. Accessed January 19, 2018.[3]

The Rising Trend of Maternal Mortality in the United States

Multiple studies have attempted to identify the reasons for the rising incidence of maternal death in the United States. Initially, the increase was deemed temporary and associated with changes in birth certificates, categorization of causes of death, or other record keeping issues.[14,15] Nevertheless, the data collection factors do not explain changes in specific states. For example, the MMR doubled within a 2-year period in one state; such a rise was unexpected in the absence of war, natural disaster, or severe economic disaster.[15] This state and others have now initiated maternal mortality review boards, frequently including midwives as board members, to directly examine records of women who have died. Such groups are not universally available across the country, however.[13]

Prominent among the potential etiologies of pregnancy-related deaths is the fact that care of pregnant women varies dramatically across the country. In many developed countries, best practices are shared and followed regardless of birth site. In the United States, there is no standard approach to treatments for complications of pregnancy or management of women experiencing an emergency in childbirth. This problem is currently the focus of many policy initiatives. For example, the California Maternal Quality Care Collaboration developed

"bundles" or standard practice protocols that were disseminated throughout the state on topics such as postpartum hemorrhage.[16] Studies found that adoption of such bundles was associated with decreases in maternal deaths, prompting the design of the National Partnership for Maternal Safety's bundles, which include one on managing obstetric hemorrhage.[13,17] These practice guidelines are a good example of how statistics drives research that first affects policy and then is translated into clinical practice.

Maternal Morbidity

Maternal morbidity is much more common than maternal mortality. As difficult as it is to obtain accurate maternal mortality data, however, morbidity data collection is even more elusive. Mortality data measure a single event or incidence. Morbidity data, by comparison, are much less likely to be recorded, suffer from a lack of standard case definitions, and frequently involve several comorbidities (e.g., an individual with multiple conditions such as severe anemia, vesico-vaginal fistula, repeated urinary tract infections, and clinical depression).

Near-miss maternal mortality is a life-threatening event that could result in death. Recent efforts to define and track near-misses have been proliferating as a method to further assess the quality of health care and the effectiveness of interventions.[18] Early warning criteria are being instituted as part of patient safety bundles in an effort to decrease the incidence of maternal morbidity.[18]

Reproductive Health: The Global Picture

Although pregnancy-related deaths in the United States are a critical concern nationally, approximately 99% of maternal deaths occur in low-resource nations, as shown in **Table 3A-4**.[19] It is difficult to compare maternal mortality ratios across nations because of inconsistency in definitions and reporting. On a worldwide basis, many women never enter the healthcare system during pregnancy, even when gravely ill, and, therefore, deaths and disabilities are not well captured in vital statistics, surveillance data, or other records. Because the maternal mortality rate is difficult to obtain, the *ratio* is used more frequently. When comparing countries, the maternal mortality ratio is the number of maternal deaths per 100,000 live births in a given period of time.

Table 3A-4 **Estimates of Maternal Mortality Ratio, Number of Maternal Deaths, and Lifetime Risk by United Nations Millennium Development Goal Region, 2013**

Region	MMR: *n*/100,000 Live Births	Range of MMR Uncertainty		Number of Maternal Deaths[a]	Lifetime Risk of Maternal Death: 1/*n*
		Lower Estimate	Upper Estimate		
World	210	160	290	289,000	190
Developed regions	16	12	23	2300	3700
Developing regions	230	180	320	286,000	160

Abbreviation: MMR, maternal mortality ratio.

[a] The MMR, number of maternal deaths, and lifetime risk have been rounded according to the following scheme: < 100, no rounding; 100–999, rounded to nearest 10; 1000–9999, rounded to nearest 100; and > 10,000, rounded to nearest 1000.

Data from World Health Organization, United Nations Children's Fund, United Nations Population Fund, The World Bank, United Nations Population Division. Trends in maternal mortality: 1990 to 2013. Available at: http://www.who.int/reproductivehealth/publications/monitoring/maternal-mortality-2013/en/. Accessed December 12, 2017.[19]

Global Factors Associated with Maternal Mortality

The most common causes of maternal mortality in low-resource nations are hemorrhage, infection, hypertension, complications during birth, and unsafe abortion.[19] Betrán et al. reported findings of a systematic review of maternal mortality in 141 countries in 2005.[20] Using standard regression models, these authors found that (1) the proportion of births assisted by a skilled attendant, (2) the infant mortality rate, and (3) national per capita expenditures on health were three factors strongly related to maternal mortality worldwide.[20]

In addition, a phenomenon known as the "three delays" has been identified as a critical determinant of maternal mortality. Once an emergency occurs in childbirth, its cause can be analyzed within the following framework, whose elements collectively prevent timely, high-quality care from reaching those most in need:

1. Delay in recognizing there is a problem and making the decision to seek care
2. Delay in reaching the appropriate level of care once the problem or complication has been recognized
3. Delay in receiving the appropriate care after arrival at the service site

The Safe Motherhood Initiative

In an effort to address some of the global factors involved in maternal and infant mortality, the Safe Motherhood Initiative held its first meeting in 1987 in Africa.[21] Another group that was organized a few years later but has similar goals is the White Ribbon Alliance. The White Ribbon Alliance includes many of the same members as the Safe Motherhood group, but is more broad based and includes international nongovernmental organizations (INGOs), government agencies, local nongovernmental organizations (NGOs), and community-based organizations in resource-limited countries. The general goals of the alliance members are to promote practices, protocols, and guidelines that facilitate women obtaining high-quality gynecologic, family planning, prenatal, delivery, and postpartum care, so as to achieve optimal

health for the mother, fetus, and infant during the perinatal period. Although the emphasis has been on low-resource countries, the action messages posted on the Safe Motherhood website can be of value to all countries, including the United States (**Table 3A-5**).[22]

Table 3A-5	Safe Motherhood Action Messages
Advance safe motherhood through human rights	
Empower women, ensure choices	
Safe motherhood is a vital economic and social investment	
Delay marriage and first birth	
Every pregnancy faces risks	
Ensure skilled attendance at delivery	
Improve access to quality reproductive health services	
Prevent unwanted pregnancy and address unsafe abortion	

Reproduced with permission from Safe Motherhood action messages. Available at: http://www.safemotherhood.org. Accessed December 12, 2017.[22]

Conclusion

There are multiple complexities involved in the definition, collection, and reporting of vital statistics that make it difficult to rely on exact numbers. Nonetheless, trends in these numbers tell a powerful story. The United States spends more on health care than any other nation in world, and the IMR has decreased in recent years. Yet, the IMR in the United States remains higher than that in many other developed nations, maternal mortality and morbidity are increasing, and racial/ethnic disparities in maternal–child health are striking.

The link between national vital statistics and clinical care of individuals may seem remote but, in fact, these statistics play an important role in each clinical encounter. The underlying etiologies of morbidity and mortality are both social and biologic in nature and, in turn, midwifery care of each woman must address social determinants of health as well as biologic indicators. Midwifery has a long and storied history of providing such care internationally, and today's midwives are charged with continuing that care.

PART II

Midwives as Primary Care Providers

LISA L. PAINE

The midwife's place in primary care for women and newborns is now well established, bringing with it an awe-inspiring responsibility to do our part to improve the lifelong health and well-being of women, their families, and their communities. Despite state-by-state variations in legislative and regulatory support for this aspect of the midwife's role, as well as irregularities in reimbursement for primary care services, midwives have embraced their role and the responsibilities that come with it.[1]

To some, the primary care provider role for midwives in the United States might appear to be a new phenomenon, but its roots harken back decades, if not centuries. This nation's first midwives were esteemed healers in their communities, and the first nurse-midwives were public health nurses, all providing elements of primary care as we know it today. Their scope of practice included general health and well-being for the whole family.[2] By the early 1970s, content had been added to midwifery curricula regarding family planning, ushering in a role beyond the maternity cycle to include well-woman care before and after pregnancy.[3] By the 1990s, competencies in primary care had been added to midwifery education and practice standards and were made even clearer in subsequent core competency revisions.[4,5]

In 1992, the American College of Nurse-Midwives (ACNM) issued its first formal statement declaring that certified nurse-midwives (CNMs) provide primary care for women and newborns.[6] This statement coincided with publication of results of a landmark prospective study than showed that 7 of 10 visits made to CNMs were by women or infants vulnerable to poor access or disparate outcomes by virtue of their race, ethnicity, age, education, income, immigration status, or place of residence.[7] By the end of the twentieth century, it had become clear that midwives can increase access to primary care services when they are integral members of the primary care workforce.

The U.S. healthcare system remains in flux, despite decades-long efforts to strengthen the

system, including passage of significant legislation in the past decade. The federal government's recognition of the midwife's primary care role is evidenced by primary care workforce expansion efforts that include Medicaid/Medicare program payment for midwifery services, federal funding for education programs that prepare midwives as primary care providers, and federal employee insurance coverage for midwifery services. More recently, however, threats to repeal legislation that has extended health insurance coverage to millions of Americans, as well as state variations in expansion of Medicaid coverage, mean that midwives will be providing primary care in an unsettled environment for years to come.[8] What remains clear, however, is that well-prepared midwives will be needed to meet the nation's substantial primary healthcare needs over time.

Current core competencies for basic midwifery practice specify the primary care content for which midwives are responsible.[4] In 2012, ACNM issued a policy statement that reaffirmed the role of midwives in primary care. This statement also affirmed midwives' roles within the patient-centered medical home, a relatively new model that incorporates improved quality of care strategies, promotes communication, and enhances efficient delivery of care in a multidisciplinary model—with the patient at the center of the partnership.[5]

Midwifery care is focused on normalcy, and the *Introduction to the Care of Women*, *Health Promotion Across the Lifespan*, *Common Conditions in Primary Care*, *Nutrition*, *Mental Health Conditions*, and *Pharmacotherapeutics* chapters in this text present the knowledge needed to help all women of all ages maintain and promote healthy lifestyles. Yet the women who receive primary care from midwives experience a range of inequities that influence their health and well-being and result in health disparities. This reality compels midwives to have an understanding of the social and economic determinants of health, and to explore the primary care role for women with complex social situations, as well as comorbid diseases, mental health conditions, and substance use disorders.[10,11]

The demographic characteristics of the U.S. population are changing, with glaring disparities in health outcomes experienced by women and children of color becoming painfully apparent. Thus attention to racial and ethnic diversity is a priority. Yet other aspects of diversity within populations cared for by midwives are also evident, such that some populations have well-documented inequalities in access and health disparities based on sociodemographic factors: young or old age, low education and low literacy, low income, religious affiliation, disability status, sexual minority status, and place of residence (especially remote, rural, or urban areas). The intersectionality of these population characteristics can further magnify health problems, as in the case of race/ethnic disparities among rural residents.[12]

To bring about equity in terms of healthcare access, outcomes, and quality, midwives must become culturally proficient care providers and, when possible, emerge as leaders in this area.[13] To do so, midwives must embark on a personal and professional journey. Cultivation of cultural humility is an essential first step in the development of the cultural competence skills needed for the practice of effective primary care.[14] Midwives must commit to the practice of cultural humility—a lifelong process of self-critique, self-awareness, and reflection. By examining their own worldview, rather than focusing solely on the client's belief system and

culturally specific traits, the midwife will appreciate those intrinsic qualities that enable individuals to attain health, happiness, and wholeness. With this understanding, the midwife can adapt primary care practice to be more patient centered and, in turn, more effective.

Regardless of their particular practice setting, midwives are certain to encounter women who experience health inequalities in any number of ways, including poor access to primary care and mental health care. Nearly half of all women in the United States live in an area with a shortage of primary care providers.[15] By joining their forebearers who practiced primary care midwifery for disenfranchised women and families with poor or no access to even the most basic health care, midwives today who embrace the primary care role and commit to advancing cultural proficiency can and will make lasting improvements in the health of the entire nation, especially when their work is combined with organized efforts to diversify the midwifery workforce to better serve the needs of all women.[13]

With these imperatives in mind, the chapters in this section present an overview of the common health conditions encountered in primary care. Readers are especially directed to the *Health Promotion Across the Lifespan* chapter, which summarizes current recommendations for primary and secondary prevention—these topics are integral to midwifery practice. It is abundantly clear that more uniform regulatory and practice environments are needed to maximize midwives' contributions to prevention and primary care. Likewise, midwives must be embraced as primary care providers within their practice settings and by the policymakers responsible for ensuring the health of the nation's people. Meanwhile, midwives can and will do their part by becoming fully prepared for the contemporary version of their historical role in primary care, thereby ensuring that the nation's women, families, and communities will be healthier in the future.

CHAPTER

4

Introduction to the Care of Women

Midwife Means “With Woman”

Midwifery is both art and science—and above all midwifery is care for women and their families. As discussed in the first chapter of this text, midwifery in the United States has grown from local efforts to care for women with few resources into a well-respected profession that offers women primary care and gynecologic services, as well as maternity, birth, and newborn care. These services are provided using an interdisciplinary approach because midwives rely on the skills of gynecologists and obstetricians, nurses, social workers, and other health professionals, just as those professionals rely on midwives for their respective expertise. Key to understanding midwifery care is recognition of the interweaving of skills and knowledge from many sources, and the willingness to work with others to achieve the best possible health outcomes for a woman.

The evidence-based studies and expert opinions that underpin the science of midwifery are the same as those from which medicine and nursing draw their understanding of health care. Unfortunately, relatively few of the expert recommendations on which clinicians rely are drawn from high-quality research. In some situations, interventions are adopted before large research studies are conducted. In brief, most clinicians practice similarly, and practice styles are often based on the preferences and experience of those who have taught them.

The flawed perception that guidelines are consistently based on solid evidence and lack bias has been acknowledged.[1] For example, in 2011 the American College of Obstetricians and Gynecologists published the finding that fewer than one-third of its Practice Bulletins were based on “good and consistent” evidence.[2] Additionally, much of pregnancy care cannot be evaluated safely and ethically using the most rigorous types of research. Midwifery research continues to account for only a small percentage of the work being conducted in the area of women’s health, although an increasing number of scholars are contributing knowledge in this area. Examples range from the development of Centering Pregnancy as a model of care to the research done on delayed cord-clamping after birth.[3,4] Deciphering the evidence, acknowledging the quality of information from which recommendations are made, and recognizing biases—both in midwives and in others—are all key components of midwifery care.

Midwifery is distinguished by characteristics that define a partnership with women. A willingness to listen; sensitivity to cultural, sexual, and generational differences; shared decision making; the patience to be “with women”—all combine with professional behaviors to describe midwifery practice. This chapter addresses both clinical tasks and professional behaviors, and its goal is to identify those core skills needed to be a midwife.

Essential skills begin with an understanding of the midwifery management process. Developed by midwifery education program in Mississippi in the early1970s,[5] the seven steps in this process serve as a guide to the process of care at an individual level and offer an opportunity to evaluate the effectiveness of care (**Table 4-1**).

Table 4-1	The Midwifery Management Process

1. Investigate by obtaining all necessary data for complete evaluation of the woman or newborn.
2. Accurately identify problems or diagnoses and healthcare needs based on correct interpretation of the data.
3. Anticipate other potential problems or diagnoses that might be expected because of the identified problems or diagnoses.
4. Evaluate the need for immediate midwife or physician intervention and/or for consultation or collaborative management with other healthcare team members, as dictated by the condition of the woman or newborn.
5. Develop a comprehensive plan of care that is supported by explanations of the valid rationale underlying the decisions made and is based on the preceding steps.
6. Assume responsibility for the efficient and safe implementation of the plan of care.
7. Evaluate the effectiveness of the care given, recycling appropriately through the management process for any aspect of care that has been ineffective.

The midwifery management process emphasizes the midwife's responsibility as an independent care provider and is based on the scientific process. Even while other practitioners may be involved in care, the midwife assumes responsibility for ensuring the woman and her family receive adequate and prompt treatment and health education.

The comprehensive plan noted in the management process focuses first on evidence-based treatment options that promote health and prevent morbidity and/or treat current conditions. These interventions encompass more than simple pharmaceuticals—they also comprise a plan of care customized to meet the woman's needs. Considerations in the design of such a plan include cost, accessibility, and convenience among other factors.

The midwifery management process also acknowledges that most care is provided not in discrete sessions, but rather over time. Optimally, continuity over time is critical in improving quality of care.

Communication

Clear communication is an essential component of any therapeutic interaction and deserves conscious attention if it is to be effective. Several important variables influence the success of communication between a midwife and a woman who seeks healthcare services.

Many characteristics that contribute to a person's identity play an important role in the relationships between women and their midwives. Cultural identity, sex and gender identity, race and ethnicity, immigration status, and socioeconomic status are just a few examples of the factors that influence a person's interactions with others. Health literacy and health numeracy impact how well an individual understands medical communications. In addition, language itself can facilitate or be a barrier to comprehension.

The Role of Culture, Race, Ethnicity, and Identity

Midwives will, over time, meet individuals who are hesitant to share their health concerns because they have learned to distrust how their beliefs and identity may be received. What does this mean for the midwife in practice? Awareness of one's own cultural assumptions, as well as appreciation of one's personal biases and choices about practice parameters, is an essential first step. Unless midwives know themselves, they are at increased risk of unconscious offenses and implicit bias that may hinder the therapeutic relationship, increase reluctance to share important information, or prevent a woman from seeking care. This is a lifelong project. Few, if any, individuals come into adulthood fully sensitive to these topics.

It is important to remember that health care is a cultural construct as well—emerging from beliefs about the characteristics of disease and the impact on the human body. Consequently, culture is a primary factor in the provision of health care that influences both the provider and the receiver of care. This idea extends not only to the care provider, but also to structural and process aspects of care. DeMeester and colleagues describe components of the healthcare system that can improve shared decision making for persons from at-risk communities, focusing on dual-minority individuals (e.g., lesbian and African American). These components include reflecting the community in office workflow, health information technology, organizational culture and structure, the physical environment, resources, staff training, and incentives for positive results.[6] In this light, it is important to note that throughout this book the term "women" is used and may on occasion include reference to individuals who do not self-identify as a "woman." It should be understood that individuals may have a sexual and/or gender identity that is different than the biologic sex at birth, as discussed in more detail in the *Midwifery: Clients, Context, and Care* chapter. Thus, the reader is encouraged to apply the information in this chapter on physical examination as is pertinent for the individual patient.

Addressing Sensitive Concerns

Midwives deal with some of the most intimate and personal aspects of a woman's life. Her choice of partner, her decisions about childbearing, and her sexual experiences constitute just a few of the themes that impact the woman's life. Her risk for being exposed to violence,

whether physically, sexually, or emotionally, is another theme. The choices she has made with regard to lifestyle or habits, exposure to infections, and whether she has basic necessities such as adequate food and shelter are all topics that can and will come up during midwifery care.

Women may experience stigma for many reasons. When a person has been exposed to negative reactions in the community enough times, that individual tends to withdraw from creating opportunities to be stigmatized. It is the midwife's job to create a safe environment, where questions can be asked and answered, and where help can be sought and offered. When greeting a woman or family in the office, when providing care, and when discussing choices, watch for physical or verbal cues that suggest that another topic needs to be addressed.

Use of Language

Learning to listen to one's own words and see one's physical position relative to others is a skill like any other. Both speech and body language affect the relationship between the midwife and the woman. Among other things, this means that word choice needs to be appropriate for the woman's educational and cultural background. The midwife has to move to where the woman is in terms of understanding; by beginning there, both can move together to identify and discuss a problem. The language that any healthcare provider spends years mastering is not the common tongue.

Active listening is an essential skill. It requires the patience to allow a woman to tell her own story where she wishes to start it, with minimal interruptions or directive language. Asking open-ended questions encourages a woman to put into her own words her concerns. When one listens actively, one focuses on what is being said, reflects back what one hears, and verifies that both participants in the conversation share understanding. Waiting silently to encourage additional information; paraphrasing an unclear statement by asking, "I think you mean ____. Is that correct?"; reflecting back, such as by saying, "I hear you saying _____."; and providing reassurance that the woman's information is important are all critical tools. Validating understanding of a problem described by a woman is essential—it is all too easy to misunderstand her actual concern. Further, the woman needs to believe that what she says will be held in confidence, and that she may safely say anything she needs to say. Active listening also incorporates a nonverbal component, including making eye contact, leaning toward a person rather than away from her, having an open body position that suggests acceptance, avoiding closed positioning (e.g., not crossing the arms), and maintaining a professional facial expression.

Another instrument for listening to oneself is to consider how communication in a professional setting affects the woman's ability to hear what is being said. The midwife's words should answer the following four questions. These questions are based on similar concepts that have traditionally been attributed to various individuals and groups, such as the mystical Sufi tradition, Socrates, and more recently, the Quakers. Although their origins may be murky, the concepts remain relevant today. The questions are appropriate when considering how communication in a professional setting affects the woman's ability to hear what is being said. The midwife's words should answer the following four questions:

1. *Is it truthful?* If not, there is no need to say it.
2. *Is it kind?* Many of the topics that need to be discussed require kindness to make it possible for the listener to accept unpalatable advice. Kindness is not ignoring a problem, nor is it patronizing the woman. For example, there are many ways to tell a woman she weighs too much and needs to lose weight. Compare "You're obese and you need to eat less" with "I'm concerned that your weight is harming your health." Which of these statements will be more likely to encourage the woman to accept a referral to a nutritionist?
3. *Is it necessary?* Preventing damage from diabetes or hypertension in this example may hinge on the woman accepting the referral and actively participating in improving her health. Do not ask a question unless the answer changes the woman's management plan, and always be able to explain to the woman why the question is needed.
4. *Is it appropriate?* In one sense, discussing weight management is always appropriate —but what if the woman has come to be treated for a sexually transmitted infection (STI)? Perhaps weight loss is not the concern she needs to focus on today.

Health Literacy and Health Numeracy

The midwife should address the woman in language she can understand, with explanations that are clear and do not omit factual information that is important. Health literacy is defined by the Institute of Medicine as "the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[7] Approximately half of the U.S. adult population has low health literacy.[8] Low health literacy is associated with more hospitalizations and lower use of preventive services such as mammography and vaccinations. Although educational attainment frequently is used as a proxy for health literacy, many individuals actually read and, more importantly, comprehend at levels below their formal educational level. Research is being conducted into the use in this electronic age of graphics, apps, and digital presentations for individuals who are not highly literate.[9,10]

Health numeracy, which is the degree to which individuals understand quantitative and probabilistic health information, is an important component of health literacy.[11] Strategies to increase the likelihood that a woman will understand the probability of an event include using absolute numbers instead of percentages, relative risks, or risk ratios;[12] avoiding the words "rare," "unlikely," "uncommon," and "unusual," as these are imprecise concepts subject to individual interpretation; and using small denominators and whole numbers.[13] For example, "1 in 4" is more easily understood than "25 out of 100" or "25%." Studies of health literacy and health numeracy often portray these abilities as individual patient skills, but effective communication by the midwife is an equally important factor in ensuring understanding.[14,15] Resources for learning more about health literacy and health numeracy are included in the Resources section at the end of this chapter.

Approaching the Woman

The first steps in any clinical encounter usually occur before the midwife and a woman meet. Somehow, the woman has found the practice, made an appointment, been checked in for her visit, and possibly been seen by a nurse or medical assistant. She has observed whether the setting is professional and the furnishings are in good repair. Although it is not the purpose of this chapter to discuss specific practice management, all of these events will have shaped the woman's first impressions of her midwife and of midwifery. Seemingly simple choices about work flow, such as whether the woman is seen first in an office or undressed on an examination table, say something about mutual respect. Just as when making a home visit, the midwife looks for clues about the woman's lifestyle and health of her family; likewise, the woman seeks clues about the midwife's practice and professionalism.

Before asking any questions, however, mutual introductions should take place. Think of the relationship forged during this encounter as a framework for the care that the woman will receive. The woman should be seated comfortably and with adequate personal space. The midwife's position should promote direct eye contact. Asking, "How are you today?" or "How are you feeling?" establishes concern for the woman as an individual. Listening to her answer assists the establishment of mutual trust and trust in midwifery care.

From a legal compliance or payment perspective, the order of the visit's elements encapsulates the essential components of care. While in this context, *compliance* refers to legal requirements (such as Medicare regulations and not the woman's agreement with the management plan) and *payment* refers to what is required to receive compensation from insurers; both incorporate standards that must be met.

Some visits will be tightly problem focused; some will be comprehensive examinations. Both types of visits follow the same sequence. All begin with the same question: "Why have you come in to see us today?" The answer establishes the chief concern of the woman—that is, the reason for the visit. The terms "concern" and "reason for coming" are less value laden than the older phrase in documentation of "chief complaint." Sometimes other, more pressing problems will become apparent during the conversation or examination, but asking about the woman's initial reason for the visit is always the starting point.

The structural components of the visit include the following: chart review of previous records and test results, history, and review of systems; the examination and any office-based tests; the assessment and diagnosis; and the decision making about future visits, tests, and treatment plus the discussion, teaching, and guidance offered to the woman. **Appendix 4A** lists standard precautions that are an essential component of any healthcare visit.

Collecting the Health History

When collecting a health history, the midwife first considers the purpose of the visit. If the woman has come for a comprehensive or general reason, the history obtained will be broader than if the visit is problem focused. Consider a new prenatal visit, which will include a complete personal, social, and family history, as well as genetic risks. Contrast it with a triage visit for nausea and vomiting of pregnancy, which will focus on the current concern, asking about exposure to spoiled food and infectious contacts, allergies, gastrointestinal disorders, and problems with nausea in any prior pregnancies.

The general principle is to work from the least invasive questions to those that require more personal exposure. When one question at a time is asked, and there is a pause to wait for each response, information is less likely to be confused or omitted. Establishing and maintaining an easy flow of dialogue and a nonjudgmental manner promotes open exchange of information. A woman should be advised that some questions are very personal, and that she is not required to answer ones that she does not wish to discuss. It may be necessary to ask particularly sensitive questions on more than one occasion before the woman is able to give a full answer. An example of a situation that may require such an approach is caring for a woman with prior abuse, as discussed later in this chapter. As the health history is completed, it is wise to ask oneself if any questions are missing or any aspect was not considered. **Appendix 4B** provides a review of the complete health history.

Review of Systems

The review of systems (ROS) bridges the divide between prior health history and the current examination. It includes recent signs and symptoms the woman has noticed, such as burning on urination or a rash. The ROS, in combination with the history, can open up more extensive lines of questioning. In many practices, the ROS is a checklist given to a woman to complete while waiting. During a focused visit, the ROS may be part of the conversation during the examination. When questions are asked well, this part of the encounter can identify further areas of concern or topics for health education.

The Physical Examination

Most examinations in women's health are screening examinations, unless the midwife is serving as the primary care provider (PCP) and the history or ROS has identified additional potential health problems that need to be explored in depth. Screening physical examinations limit the details that can be elicited when every organ system is fully evaluated. **Appendix 4C** outlines a comprehensive physical examination.

By tradition, a woman's initial health assessment, whether she is pregnant or not, is comprehensive, meaning that it includes all the major organ systems. Women who see their midwife regularly and have another provider designated as a PCP can receive a "single system" examination that targets and more completely evaluates the genitourinary and reproductive systems. In that case, the thyroid, breasts, abdomen, and pelvis are examined fully, but other systems are not addressed. Because the breast and pelvic examinations are key to any women's health assessment, these components of the physical examination are reviewed in **Appendices 4D** and **4E**.

In-Office Laboratory Testing

A final part of the office examination is the completion of any in-office tests to be performed. Some tests are obtained and sent for analysis, whereas others are performed in the office and the results determined by the individual performing the test. The latter often are termed point-of-care testing. Among the point-of-care tests commonly performed in midwifery offices are urine dipstick, saline and potassium hydroxide (KOH) slides to test for the presence of yeast, trichomoniasis, or bacterial vaginosis, and pregnancy tests (**Appendix 4F**).

CLIA regulates tests performed in an office (42 CFR part 493).[16] The CLIA regulations are federal regulatory standards for all clinical laboratory tests done on humans in all settings except research protocols. CLIA identifies three categories of laboratory tests based on the complexity of test methodology: (1) waived tests, (2) tests of moderate complexity, and (3) tests of high complexity. Waived tests are those that are accurate (i.e., the likelihood of erroneous results is negligible), pose little risk of harm if performed incorrectly, and have been cleared by the Food and Drug Administration (FDA) to be performed at home. Examples of waived tests and tests of moderate complexity are listed in **Table 4-2**.

Table 4-2	CLIA Testing Categories: Waived and Moderately Complex
CLIA Waived Tests	**CLIA Tests of Moderate Complexity**
Dipstick or tablet reagent urinalysis (nonautomated) for bilirubin, glucose, hemoglobin, ketones, leucocytes, nitrates, pH, protein, specific gravity, and urobilinogen	Provider-performed microscopy: all direct wet-mount preparations for the presence or absence of bacteria, fungi, parasites, and human cellular elements
Fecal occult blood	All KOH preparations
Ovulation tests: visual color comparison tests for luteinizing hormone	Postcoital direct, qualitative examinations of vaginal or cervical mucus
Urine pregnancy tests: visual color comparison tests	Qualitative semen analysis (limited to the presence or absence of sperm and detection of motility)
Blood glucose by glucose monitoring devices cleared by the FDA specifically for home use	Fern tests
Diagnosis of STIs or vaginal conditions: HIV, trichomoniasis, bacterial vaginosis	Pinworm examinations
	Urine sediment examinations
	Nasal smears for granulocytes
	Fecal leukocyte examinations

Abbreviations: Clinical Laboratory Improvement Amendments, CLIA; FDA, U.S. Food and Drug Administration; HIV, human immunodeficiency virus; KOH, potassium hydroxide; STIs, sexually transmitted infections.

Accurate results require correct performance of even the simplest test. When the Centers for Disease Control and Prevention (CDC) surveyed laboratories performing waived tests, high rates of errors in quality control and documentation were noted; a document regarding best practices in laboratory testing was subsequently published.[17]

If *only* waived tests will be performed in an office, then a Certificate of Waiver can be obtained to license the office laboratory. The Centers for Medicare and Medicaid Services (CMS) provides explanations of the waiver process and requirements on its website.[18] CLIA tests that are of moderate and high complexity require further registration and documentation.

Provider-performed microscopy, for example, is considered a subcategory of moderate-complexity testing. Information on obtaining a license for an office laboratory can be found in the current CLIA regulations.[19]

Establishing a Differential Diagnosis: Making an Assessment

When all the information available during the visit has been gathered, the midwife makes an assessment based on a differential diagnosis. The "differential" summarizes the various conditions, disorders, and health problems that might be the cause of each identified concern. It is sometimes very straightforward—for example, assuming a woman has come for an annual examination, she is in good health, and her only questions were about choosing a birth control method, the assessment addresses her normal examination findings and the contraceptive counseling or initiation of a method that is appropriate. At other times, the differential diagnosis can be complex. Right lower quadrant abdominal pain in a woman in early pregnancy may be appendicitis, an ectopic pregnancy, a corpus luteum cyst, or any of many other possible disorders. Those conditions that have the most risk are the first differentials considered, followed by those that are most common. The symptoms, history, and examination findings are considered to determine the most likely cause.

Sometimes the initial differential diagnosis will be descriptive rather than diagnostic. In the second example in the preceding paragraph, ectopic pregnancy will always be the first condition considered, as it can cause irremediable harm to the woman.

The differential diagnosis suggests avenues for further testing or evaluation and helps to direct the plan. Continuing with the example of the woman with right lower quadrant (RLQ) pain in early pregnancy, the initial diagnosis is descriptive: RLQ pain during pregnancy. The first tests ordered should be a pelvic ultrasound and a quantitative level of serum human chorionic gonadotropin (hcG).

Designing a Plan

The plan should always include any lab work or procedures ordered, any medications prescribed, and the date of the next visit. For midwives, however, the plan never includes just these three items. Among the *Hallmarks of Midwifery* are health education, counseling, and guidance.[20] Every plan for every woman includes documentation ensuring that these aspects of care were addressed. The reputation of midwifery rests in part on midwives' ability to be available for support, knowledge, and clarity of information. The education and counseling sometimes include just-in-time teaching, such as what a group B *Streptococcus* (GBS) screening culture is and why it is recommended at the 36-week prenatal visit; at other times, they consist of information that addresses long-term plans—for example, new Pap testing guidelines and why the intervals are changing. The plan also includes information that will lead to shared decision making.

Shared Decision Making

The midwife is responsible for providing evidence-based information; the woman is responsible for considering the alternatives, asking questions, and making the decision. There are only rare occasions where professional judgment can override a woman's consent; most of these involve potentially fatal emergencies requiring rapid action. Even then, there are limitations on action—some decisions require consent of a family member or even court approval.

Shared decision making is different from presenting risks and benefits. Woman-centered decision making can occur only when risk, benefits, and the range of available options are clearly communicated. When information is presented in this way, the woman is able to make her decision within the context of her personal values and beliefs and preferences.

Midwives have the responsibility to verify that women are pleased with the amount and type of information received, and feel that their needs have been addressed during a visit. *Informed consent* and *informed refusal* are the traditional terms for documenting a woman's agreement or disagreement with a procedure or plan of care, whereas *shared decision making* encompasses both types of informed decisions but does not imply that a plan of action is simply presented to the individual. The term "informed consent" continues to be a common term in practice, however, and has been codified in several legal documents, especially those stating that the healthcare provider must legally and/or ethically obtain this type of consent before administering a treatment or procedure.[21,22]

Educational and financial status have been shown to affect an individual's preferences for shared or directed decision making: As the disparity between the care provider and the individual widens, the information provided and the path to a decision change.[23]

Studies have concluded that care that uses evidence-based, shared decision making has the potential to improve quality and outcomes.[24,25] For the most effective results, the process should be thought of in terms of shared decision making, as such a process allows for the woman to question and/or decline treatment in whole or part (i.e., make an informed consent or informed refusal). **Table 4-3** summarizes the essential components of informed decision

making.

Table 4-3	Essential Elements to Make an Informed Decision
The known or possible diagnosis	
The nature and purpose of the proposed treatment or procedure	
The benefits and risks associated with the recommended or usual plan	
Complications and side effects (include both common and severe)	
The likelihood of success for this individual	
Reasonable alternatives available, including no treatment	
Benefits and risks associated with the alternatives	
Possible consequences of not following the proposed plan of care	
Assessment of the person's understanding and agreement	

Ethical behavior requires that no harm be done (nonmaleficence), that the midwife acts for the good of the family or community involved (beneficence), that all persons are treated equally (justice), and that the woman be able to make a choice (autonomy). It is sometimes difficult to accept that the choice a woman makes is not the one a midwife is comfortable with, or even an option under initial consideration.

When a midwife cannot or does not provide a requested service, the obligation is to advise the woman about resources in an unbiased manner. The woman's ability to choose is impaired when the line between personal beliefs and professional actions is not clearly drawn. No midwife should act in a way that violates her or his understanding of safety for the woman and evidence-based care. Likewise, no midwife should withhold information or care based on her or his personal beliefs. When a woman's chosen action is outside the scope of midwifery care, whether because of its complexity or because it implies a lack of safety for the woman (or her embryo/fetus if she is pregnant), then the midwife is obligated to refer the woman to another provider.

Conclusion

The expert midwife has mastered the skills of history taking, examination, diagnosis, and treatment. She or he has become comfortable teaching, guiding, and caring for women throughout their lives. Using solid evidence as a base for decisions and focusing on safety for women will have become second nature. Equally important, the expert midwife has moved beyond simple performance of the necessary elements of care to a level where each woman is viewed as an individual and as a member of her community, to respect different cultures and become culturally competent in delivering healthcare services, and to truly believe that all women deserve midwifery care.

Standard Precautions

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

Healthcare-associated infections (HAIs) are any infections that individuals acquire while receiving direct services. It has been estimated that HAI rates range from 5% to 35%.[1] Although activities designed to prevent HAIs were originally targeted toward protection for consumers, healthcare workers are also at risk for HAIs. Therefore, knowledge and institution of standard precautions are a core standard of practice to protect both the women and families for whom midwives provide care, as well as the midwives themselves.

Standard precautions are the essential activities that should be employed by all healthcare workers in all healthcare settings for the purpose of preventing HAIs without regard to specific infection risks. Standard precautions are the most basic level of infection control and have four components: (1) hand hygiene, (2) use of personal protective devices, (3) safe injection practices, and (4) respiratory hygiene/cough etiquette.

Standard precautions[2] are sometimes viewed as interfering with the close relationship valued both by midwives and by women. However, they are also the most effective method of preventing *both* parties from accidentally being exposed to infection. On some occasions it is the midwife who is more at risk when caring for a woman with an infection than the woman herself. Standard precautions are not limited to the hospital environment, although some accommodations to precautions are observed in ambulatory settings.[3] For example, complete contact precautions are not always possible when a woman presents with an open lesion that was not previously disclosed.

Standard Precautions

1. Hand hygiene is to be performed before and after every encounter with an individual, regardless of the healthcare environment—hospital, home, birth center, or office. Alcohol-based cleaners are effective against a wider spectrum of pathogens than soap and water and are preferred unless the hands are visibly soiled. Soap and water are

always used when any dirt, blood, or body fluids are visible.[4]

2. Gloves are worn for vaginal examinations; collection of cultures; birth; phlebotomy, finger sticks, and heel sticks; handling the newborn before the baby is washed and dried; and handling of any sanitary or bed pads, clothing, linens, or other items soiled with body fluids. Hand hygiene is always performed after glove removal.
3. Personal protective equipment (PPE) is used to prevent exposure of skin and mucous membranes (eyes, nose, mouth) to blood, amniotic fluid, vaginal secretions, semen, repeated contact with breast milk, and body fluids or secretions containing visible blood. PPE can include gloves, cover gowns or aprons, masks, protective eyewear, foot covers, and mouthpieces or other barriers for use during resuscitation.
4. Safety needles have mechanisms built in to protect providers from accidental needle punctures. Blunt-tipped needles are advised for drawing up fluids from a vial to minimize needle-sticks associated with sharp needles. Both safety syringes/needles and blunt needles should be used whenever available. Needles are *not* to be recapped, removed from disposable syringes, bent, broken, or otherwise manipulated by hand after use. All sharp needles and disposable instruments should be placed in puncture-resistant disposal containers located in the immediate area, but outside the reach of visiting children.
5. Respiratory hygiene is observed to protect against respiratory and other droplet infections. This includes provision of tissues, masks, and hand cleaner in all healthcare settings; a reminder to women and their family members who are ill to cover coughs or sneezes and utilize the provided supplies; and seeing that all healthcare staff also observe these precautions.

4B

Collecting a Health History

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

In women's health, the chief concerns, or reasons for a visit, are frequently focused on reproductive or gynecologic concerns. This does not mean that the personal health or family history can be omitted. A woman's overall health influences healthcare decision making, as prior illnesses and surgeries may affect which type of examination is indicated and which medications can be prescribed. Family history may open up a discussion about future health risks. For midwives with an active primary care practice, many general health concerns, elicited in the history and review of systems, may also be addressed during routine examinations.

History of the Present Illness

After determining the chief concern for a visit, the next step is to inquire about the history of the present illness (HPI). This is often a misnomer—for example, the reason for a visit of "I need my Pap test and birth control pills" leads to an HPI that addresses how the woman is managing her contraception and her satisfaction with her current method (and possibly to a discussion of screening recommendations). A chief concern that begins with abnormal uterine bleeding leads to the more traditional assessment of the history of the woman's current symptoms. A common mnemonic for the questions asked about a health problem is OLD CARTS (**O**nset, **L**ocation/radiation, **D**uration, **C**haracter, **A**ggravating factors, **R**elieving factors, **T**iming, and **S**everity). These questions can be followed by "What has changed now that made you come in?" or "How did you decide it was time to come in?"

Past Health History

A past health history includes review of all the organ systems, mental health, common infections, blood transfusions, injuries and traumas, and surgeries including any complications

(**Table 4B-1**). The list in Table 4B-1 is not comprehensive, but does include questions that are frequently or specifically germane in a woman's health examination. Clearly, any other problems that are identified should also be investigated.

Table 4B-1 Past History

1. Neurologic	**2. Skin**	**3. Respiratory**	**4. Cardiovascular**
Migraine headaches	Chronic skin conditions	Asthma	Hypertension
Other types of headaches		Tuberculosis	Hyperlipidemia
Epilepsy or seizure disorders			CVA
Multiple sclerosis			Myocardial infarction
5. Breast	**6. Gastrointestinal**	**7. Genitourinary**	**8. Musculoskeletal**
Regularity of self-breast examinations	GERD	Frequent UTIs	Arthritis
Biopsy, cyst or adenoma removal	Chronic diarrhea or constipation	Genital tract infections	Any limitations of motion
Breast enlargement, reduction, or reconstruction	Cholecystectomy	STIs	
Other breast problems	Appendectomy	Hysterectomy, myomectomy, oophorectomy	
	Bariatric surgery	Post childbirth repair	
		Cervical LEEP, cone biopsy	
		Maternal DES exposure	
9. Hematologic	**10. Endocrine**	**11. Infections**	**12. Psychological**
Sickle cell, hemoglobinopathies	Thyroid disorders	Childhood infections	Depression
Anemia	Diabetes	Vaccinations, especially TDaP and influenza	Postpartum depression
Bleeding disorders		Chronic illnesses—HIV, hepatitis B or C, herpes	Other mental disorders
		PID	
		Endometritis	
13. Allergies	**14. Medications**	**15. Other**	**16. Risk of violence**
Drug	Prescription	Surgeries	Physical, sexual, or emotional
Environmental	Vitamins	Physical trauma	Violence: current/past
Food	Over the counter	Injuries	Abusive behavior: current/past
	Herbal, homeopathic, nutritional, or other supplements		

Abbreviations: CVA, cerebral vascular accident; DES, diethylstilbestrol; GERD, gastroesophageal reflux disease; HIV, human immunodeficiency virus; LEEP, loop electrosurgical excision procedure; PID, pelvic inflammatory disease; STI, sexually transmitted infection; TDaP, tetanus, diphtheria, pertussis vaccine; UTI, urinary tract infection.

Some commonly asked questions include the following:

1. Have you ever had a major illness—for example, any breathing problems, stomach or liver problems, or any bladder infections?
2. Are there any other problems you can think of?
3. Have you ever had to have any special tests or procedures?

4. Have you ever been admitted to the hospital because you were sick? When was that? Why were you in the hospital?
5. Who has been taking care of you for (problem)? Have they suggested you see anyone else?

For the woman who is seen on a regular basis, asking whether there has been any change in her health, and possibly reminding her of what she previously reported, can assist with time management during the visit.

Social History

The social history, like the sexual history, brings up topics that may be embarrassing or even threatening to some women (**Table 4B-2**). Ask these questions in a quiet, professional tone, and respect the woman's need to avoid certain answers. Providing information "why" the information is needed often reassures the woman and may help the midwife feel comfortable asking for it. Obviously if there is no reason for eliciting sensitive information, asking it should be omitted. Relationship questions should be asked in a pattern that allows women to reveal relationships that are more complicated than "single" or "married with children."

Table 4B-2 Social History

1. Relationship status	2. Diet	3. Substance use	4. Employment/student status
With a partner (male or female) Married Single Widowed, separated, or divorced	Eating habits, history of eating disorders Diet recall Any food restrictions—allergies, vegetarian or vegan, religious, cultural limitations	Caffeine Tobacco Alcohol Marijuana Illicit drugs Use of others' prescriptions	
5. Hazardous exposures at work or home	**6. Physical activity, types and frequency**	**7. Seat belt use**	**8. Guns or weapons in home**

Gynecologic and Pregnancy History

This area is a natural progression after the general history is taken, and some of the items mentioned previously need not be re-asked if the answer is already recorded. Listen for answers to questions not yet asked and note them (**Table 4B-3**).

Table 4B-3 Gynecologic and Pregnancy History

1. Last menstrual period and last regular menstrual period	**2. Age at menarche, timing of menstrual cycles** Any irregularity of timing Amount and duration Premenstrual symptoms Dysmenorrhea Endometriosis	**3. Perimenopausal symptoms** Age at menopause—surgical or natural Use of hormone therapy	**4. Pap test history** Abnormal Pap test Colposcopy Cervical treatment or surgery
5. Contraceptive history[a] Types used Duration of use Any problems	**6. Age at onset of sexual activity** Additional information in the sexual history in Table 4B-4	**7. Pregnancy** G/P-TPAL Gravida (number of pregnancies) Para (number of births); T: term; P: preterm; A: spontaneous or elective abortions; L: number of living children Ectopic and multiple pregnancies Problems with pregnancies, births, or recovery Genetic testing Postpartum depression	**8. Other** Infertility Reproductive life plan or childbearing plans

[a] If a woman has had only women partners or is abstinent, she may have had no need for contraception, but may have still chosen to use hormonal contraception for other benefits.

Sexual History

Core questions, such as age at first coitus, number and gender of partners, and if the woman is currently sexually active or not, are asked as part of a general gynecologic history. Nevertheless, the Centers for Disease Control and Prevention recommends obtaining a complete sexual history during an initial visit, as part of routine preventive examinations, and for any woman who presents for care of possible sexually transmitted infections.[1,2] The sexual history is based on the "5 P's"—**p**artner, **p**ractices, **p**rotection from STIs, **p**ast history of STIs, and **p**revention of pregnancy (**Table 4B-4**). Because this topic can be difficult, it may help to introduce it by telling the woman that these questions are asked of all adults and the information is kept in confidence. The CDC also has a Brief Sexual History Tool that can be filled out privately by the woman and then reviewed during the visit.[2]

Table 4B-4	**Sexual History**
1. Partners	
Are you sexually active? If no: Have you ever been sexually active?	

If yes: Are your sexual partners men, women, or both? (If the individual answers “both,” ask the next questions about partners for each sex and gender partner.)
In recent months, how many sex partners have you had?
What is the sex and gender of your previous sexual partners, including men, women, and transgender individuals?
Do you have any problems with your sexual partner, or does your sexual partner have any problems you want to discuss?
2. Practices
Have you ever had oral sex, meaning mouth on penis or vagina sex? How many times have you had oral sex without a condom or dental dam? Do you have receptive oral sex, meaning when the male ejaculates into your mouth?
Have you ever had vaginal sex, meaning any type of sex that involves insertion of objects into your vagina? Which objects are inserted into your vagina? Are you the receptive partner in female–male intercourse, meaning that the male ejaculates while in your vagina? How many times have you had vaginal sex without a condom or used safe sex practices?
Have you ever had anal sex, meaning penis in rectum/anus sex? Are you the receptive partner, meaning that the male ejaculates into your rectum? How many times have you had anal sex without a condom?
Are your sexual practices more painful than you would like?
If yes: Explore for sexual violence, dyspareunia, and other sources of pain.
3. Protection from Sexually Transmitted Infections
Do you use anything to protect yourself from STIs like HIV?
If no: Can you tell me the reason?
If yes: Which kind of protection do you use and how often do you use it?
Do you have any questions about methods to protect against STIs?
4. Past History of STIs
Have you ever had an STI?
If yes: How were you treated for it?
Have you ever been tested for HIV or other STIs? Would you like to be tested?
Have you had any recurring symptoms?
Has your current sexual partner or former partners ever had an STI, including HIV?
If yes: Were you tested at the same time?
5. Prevention of Pregnancy
Are you currently trying to conceive a child?
Are you concerned about getting pregnant?
Are you using any form of birth control? Do you need information about birth control?
6. Additional Questions
What other things about your sexual health or sexual practices would you like to discuss?
Do you have any other concerns or questions?

Abbreviations: HIV, human immunodeficiency virus; STI, sexually transmitted infection.

Family History

Family histories assist in identifying risk factors and genetic concerns. Some concerns may be a disease or condition; other factors may relate to psychological or social concerns. The health histories of first- and second-degree relatives are most important. Minimum components include the elements listed in **Table 4B-5** for parents, siblings and grandparents.

Table 4B-5 **Family History (Three Generations)**

1. Parents and siblings	2. Chronic disorders	3. Genetic problems
Living or dead	Heart disease—especially coronary artery disease	Birth defects
Age at death	Diabetes	Mental handicaps
Cause of death	Cancer—especially breast, reproductive, or colon	Behavioral conditions

The final question in the history taking should be some variant of "Is there anything else I should have asked you today?" or, alternatively, "Is there anything else I should know or that you want to share with me?"

Review of Systems

The review of systems (ROS) acts as a bridge from the past to the present. It is a structured inquiry about current symptoms or concerns related to each body system. This part of the examination serves as a check for symptoms that the woman may be experiencing but has not yet mentioned. **Table 4B-6** is an example of a self-administered ROS form that women can complete while waiting for the visit with the midwife. In some practices, a standard screening tool for depression is also provided for women to fill out privately before the visit. Alternatively, an ROS may be completed with the physical examination, asking the woman about symptoms as the examination progresses.

6. Respiratory
- ❑ painful breathing
- ❑ wheezing
- ❑ short of breath
- ❑ chronic cough
- ❑ spitting up blood

7. Cardiovascular
- ❑ chest pain or pressure
- ❑ leg swelling
- ❑ difficulty breathing when active
- ❑ rapid or irregular heartbeat

8. Breasts
- ❑ pain in breast
- ❑ breast lump
- ❑ nipple discharge

9. Gastrointestinal
- ❑ frequent diarrhea
- ❑ bloody stools
- ❑ nausea/vomiting
- ❑ constipation
- ❑ passing gas or stool involuntarily

10. Genitourinary

- ❑ blood in urine
- ❑ pain with urination
- ❑ frequent urination
- ❑ incomplete emptying of bladder
- ❑ unintended urine leaking
- ❑ leaking urine with cough or lifting
- ❑ abnormal vaginal bleeding
- ❑ painful periods
- ❑ pain with sex
- ❑ premenstrual symptoms (PMS)
- ❑ abnormal vaginal discharge
- ❑ hot flashes

11. Muscle and skeletal

- ❑ muscle weakness
- ❑ spasms
- ❑ muscle or joint pain
- ❑ frequent falls

12. Hematologic and lymphatic

- ❑ frequent bruising
- ❑ enlarged lymph nodes
- ❑ cuts that do not stop bleeding

13. Endocrine

- ❑ hair loss
- ❑ heat/cold intolerance
- ❑ abnormal thirst
- ❑ hot flashes

14. Mental Health

- ❑ mood swings
- ❑ frequent crying
- ❑ anxiety
- ❑ trouble sleeping
- ❑ thoughts of hurting yourself or someone else

15. Allergies

- ❑ hay fever
- ❑ hives
- ❑ seasonal allergies
- ❑ latex allergy
- ❑ food allergies

The Physical Examination

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

As with the health history, this description of the physical examination focuses on those aspects most significant for women's health. Be alert for any inconsistency between the woman's history and the physical examination.

Review of General Principles

1. As with every healthcare visit, hand washing is essential immediately prior to beginning the examination. Alcohol-based gels and/or foams are appropriate. Hand washing within the woman's vision may be reassuring to her.
2. Ask the woman whether she has any area of her body in particular that she wants to have examined.
3. Drape the woman in such a way that only the area being examined is exposed. The approach can demonstrate respect for her body as well as respect for her right to modesty and privacy.
4. The examination should progress from head to toe, and minimize the number of times the woman has to change position (**Table 4C-1**).

Table 4C-1	Physical Examination	
1. Constitutional Findings	**2. Neurologic**	**3. Skin**
Measured height and weight, calculation of BMI	Orientation to time, place, and person	Normal tone and turgor
Vital signs: blood pressure, pulse, respiratory rate, temperature	Cranial nerves (visible alterations)	Rashes, boils, or lesions
General appearance, grooming, cleanliness	Mood and affect Depression score (if formal assessment done)	

4. Head and Neck	5. Respiratory	6. Cardiovascular
Eyes with PERLA	Lung sounds	Heart rate and rhythm
Dental care needed	Respiratory effort	Audible murmurs or extra heart sounds
Thyroid		Pulses
Enlargement of lymph nodes		Varicosities
7. Gastrointestinal	**8. Genitourinary**	**9. Musculoskeletal**
Abdominal tone, guarding, rigidity	CVAT (as illustrated in *Common Conditions in Primary Care* chapter)	Spinal deformity
Bowel sounds	Suprapubic tenderness	Range of motion
Size of liver and spleen, masses	See Appendix 4E	DTR
Hernias, inguinal lymph nodes		Clonus (as described in detail in *Complications During Labor and Birth* chapter)
Rectum (hemorrhoids, fissure)		

Abbreviations: BMI, body mass index; CVAT, costovertebral angle tenderness; DTR, deep tendon reflex; PERLA, pupils equal and responsive to light and accommodation.

5. Talk as the examination proceeds, both to let the woman know what is happening next and to share reassuring findings. Alert the woman in advance if any part of the examination will be uncomfortable.
6. Use a touch that is as firm as needed to elicit accurate information.
7. Share the findings with the woman. If she is anxious about something that is normal, describe why the examination is normal.
8. Discuss physical changes that may be abnormal with the woman briefly during the examination and in more detail after she is dressed at the end of the visit.

APPENDIX

4D

Breast Examination

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

Clinical examination of the breasts takes place while taking into consideration any concerns expressed by the woman, any relevant personal or family history, and review of any prior records or reports. Formal breast self-examination is no longer recommended, but rather has been replaced by "breast awareness" as a way to encourage women to recognize abnormal changes between clinical evaluations. There is no consensus about the clinical breast examinations.[1-5] Neither the American Cancer Society[2] nor the U.S. Preventive Services Task Force[3,4] recommends regular clinical breast examination for asymptomatic women. The American College of Obstetricians and Gynecologists continues to recommend offering clinical breast examinations to women at average risk for breast cancer every 1 to 3 years for women aged 25 to 39 years and annually starting at age 40 years.[5] More information on breast evaluation and diagnosis is found in the *Breast Conditions* chapter.

Procedure for Breast Examination

1. Wash hands prior to beginning the examination.
2. The woman should be seated on the examining table so that she is facing the examiner. Her chest area should be entirely exposed. Throughout the examination, use the drape or gown to cover any parts of the woman's body not being examined.
3. Have the woman sit erect, facing the examiner. Look at the breasts with her arms loose at her sides, raised overhead, and then with her hands on her hips so that her elbows are extended 90 degrees from the plane of her abdomen. Ask her to lean forward to check that the breasts hang freely.
   a. With her arms raised, the pectoral fascia is elevated. If there is a carcinoma that has attached to the fascia, the breast may show an indentation in the contour or skin retraction. When her hands are pressed against her hips, the pectoral muscles contract and if there is a carcinoma that is fixed to the underlying fascia, the breast

may elevate more than expected or skin dimpling or nipple deviation may occur. Similarly, when leaning over, the breasts will normally fall freely away from the chest but may exhibit asymmetry or retraction if the fibrosis of a breast lesion is present.

b. Note any visible scars.

4. Palpate the lymph nodes above and below the clavicle on both sides.

5. Ask the woman to lie supine on the table, and have her raise one arm and fold it behind her head or across her forehead.

a. If she has expressed concern about a possible mass or lesion, the opposite breast should be examined first.

6. Gently palpate the axillary lymph nodes. The palpating hand should be moved within the axilla to press anteriorly for the pectoral nodes, posteriorly for the subscapular nodes, along the upper arm for the lateral brachial nodes, and deep in the middle for the central axillary nodes (**Figure 4D-1**).

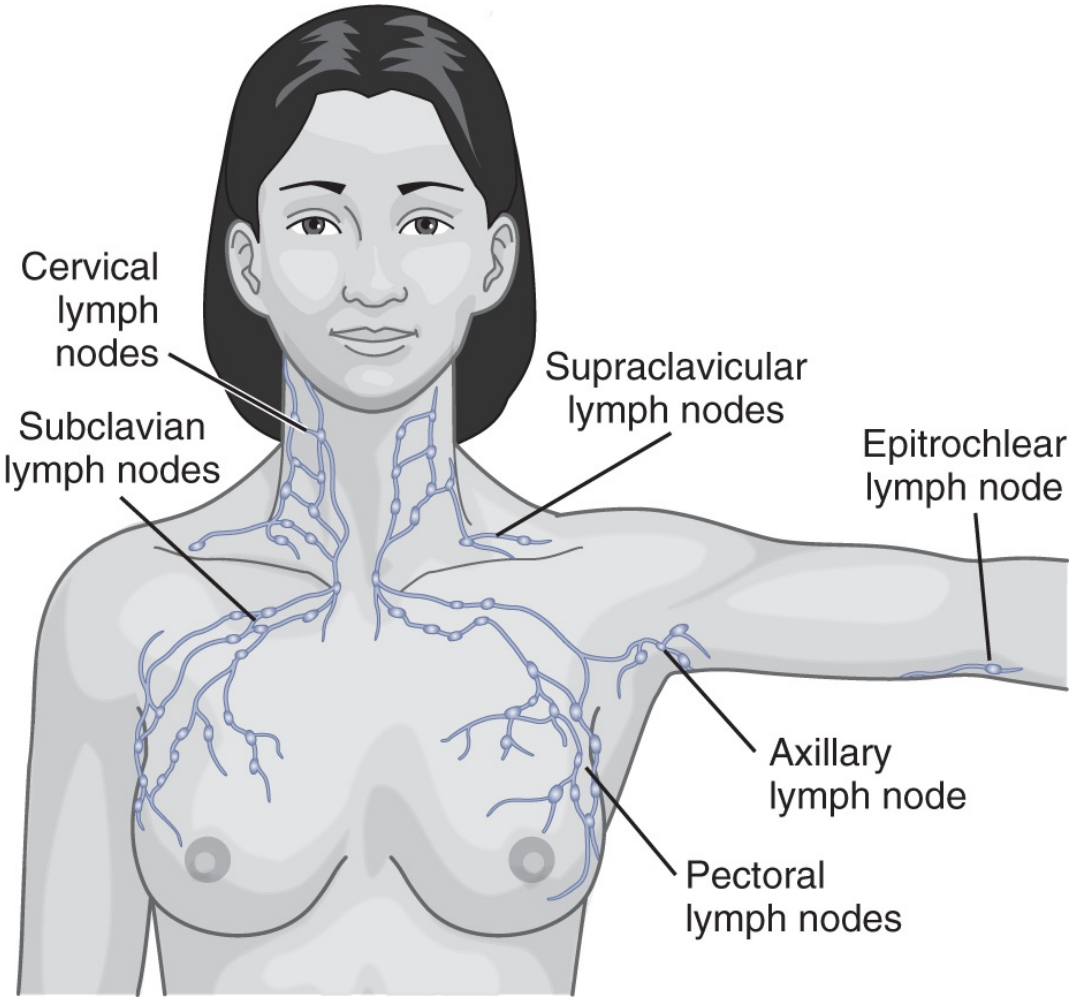

Figure 4D-1 Lymph nodes in the superficial region of the chest and the axillary region.

a. Small isolated lymph nodes that are palpable may reflect irritation from shaving or a localized infection. They should be reevaluated within 1 month.

7. Inspect the appearance of the nipples and areolae.
   a. Nipples may be erect, flat, or inverted. The appearance changes with reproductive maturity, pregnancy, breastfeeding, and aging.
   b. Spontaneous discharge, cracking, lesions, and bleeding are abnormal.
   c. Do not squeeze the nipple in an attempt to elicit discharge.
8. Inspect the appearance of the breasts.
   a. Skin texture and appearance change over time.
   b. Edema, redness, retracted or collapsed areas, visible sores, and masses are all abnormal observations.
9. The most effective pattern for clinical breast examination works up and down the breast, beginning under the axilla and working toward the sternum, and from the clavicle to below the inframammary ridge (**Figure 4D-2**).

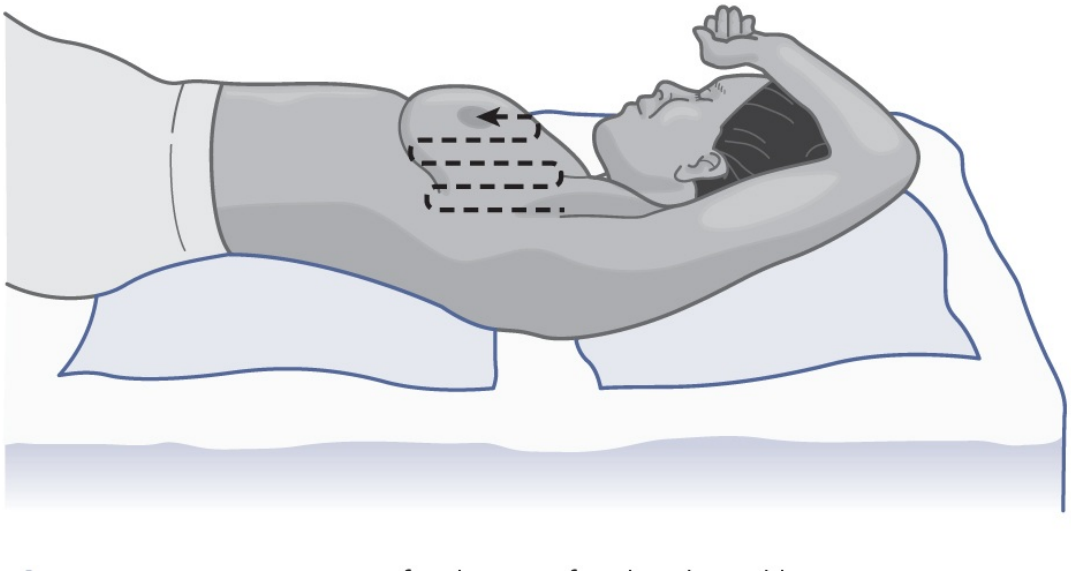

Figure 4D-2 Direction of palpation for the clinical breast examination. Begin under the axilla and move fingers down the length of the breast tissue from the clavicle to the inframammary ridge then up the length of the breast tissue from the inframammary ridge to the clavicle gradually moving toward the sternum until all the breast tissue has been palpated to three different levels of pressure.

10. Palpate each breast for texture and masses. Using the flat surface of the fingers, gently palpate each area being assessed, as illustrated in **Figure 4D-3**. A circular motion is used each time the fingers are placed on the breast. This should not be confused with an older method of breast examination in which the direction of palpation was circular—that method is no longer recommended.

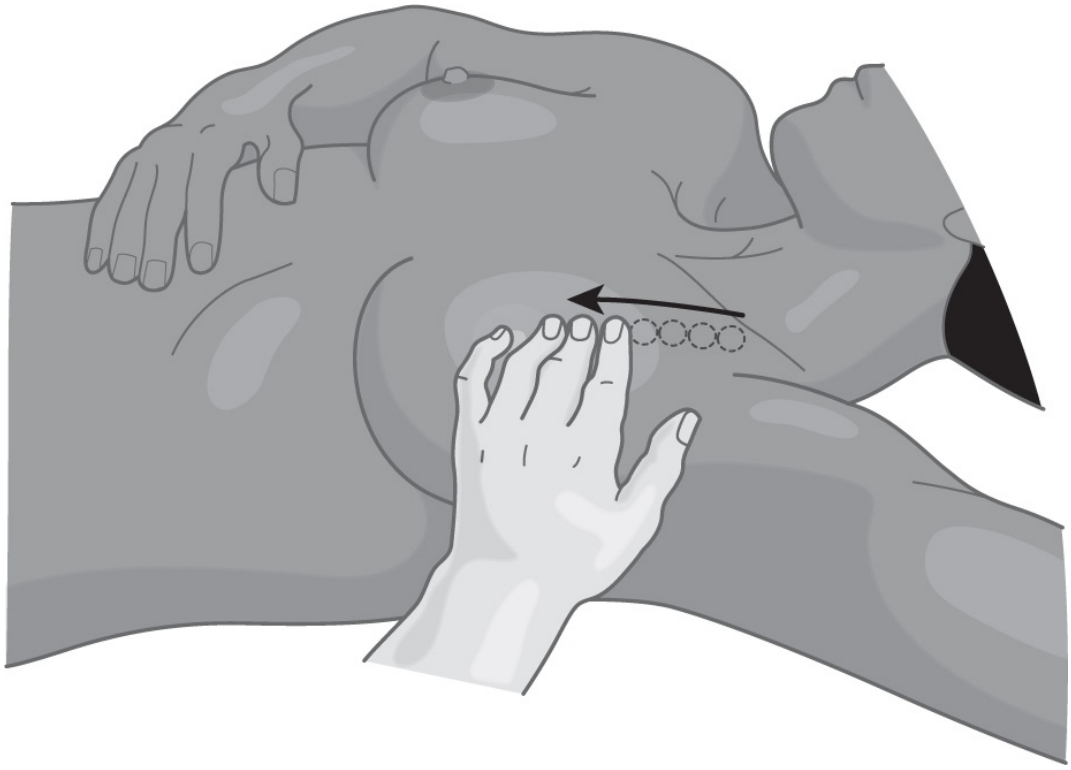

Figure 4D-3 Palpation technique for clinical breast examination.

11. The full depth of the breast to the underlying rib cage is examined (**Figure 4D-4**).

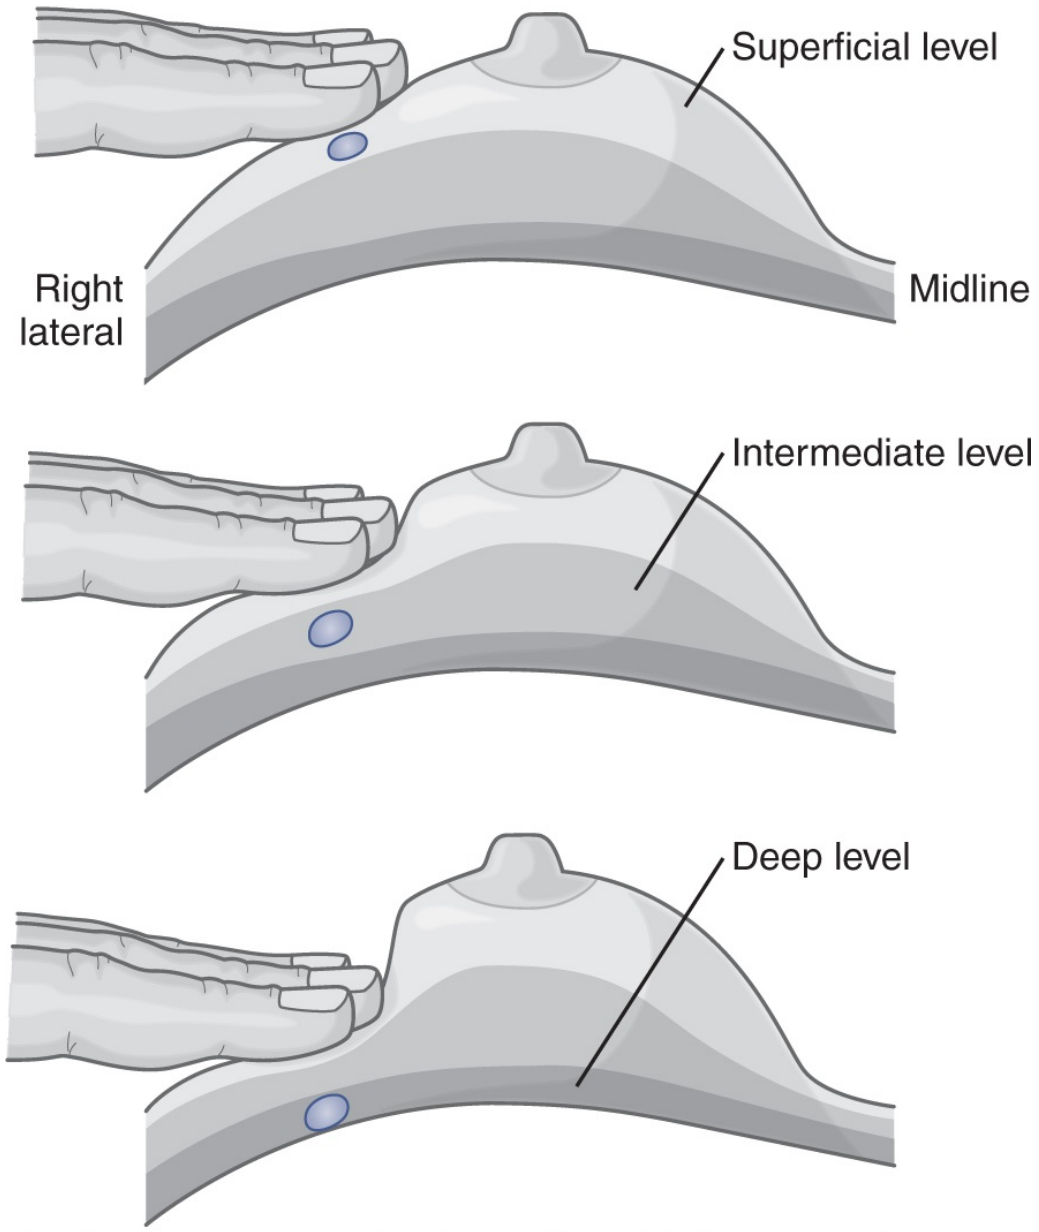

Figure 4D-4 Palpating breast tissue to three different levels of pressure.

a. Breast tissue has texture. Some young women will have very smooth tissue, while an older woman who has breastfed may have an all-over nodular texture. The texture of the breast should be consistent.

b. Prior to the menses, coarse nodularity or firmness may be more noticeable.

c. Palpable masses of any kind need to be evaluated further (**Figure 4D-5**).

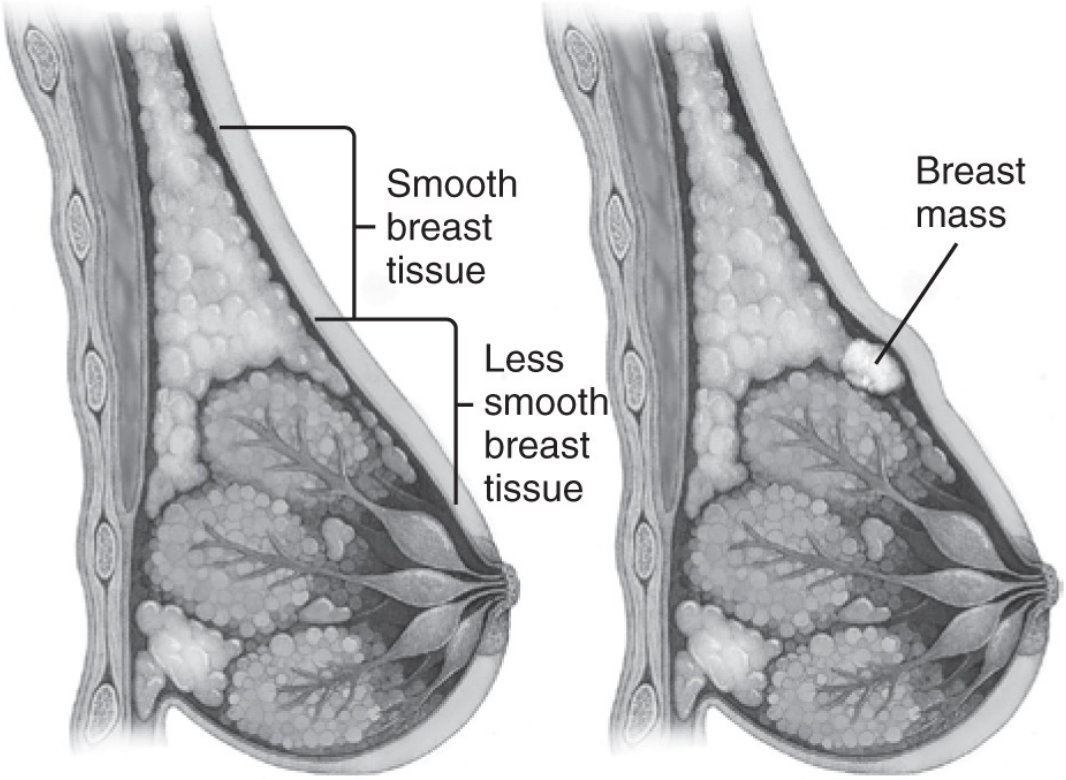

Figure 4D-5 Nodular breast texture versus a mass.

12. While performing the breast evaluation, the examiner describes what is being felt and explains how a woman can recognize breast changes. If the woman wishes to learn self-examination, this is the appropriate time to illustrate the procedure.

Pelvic Examination

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

The pelvic examination is performed based on a woman's reported concerns, personal history, and family history. Prior to beginning the pelvic examination, the midwife should determine whether the woman previously has had a pelvic examination, and if she has any concerns, questions, or history of problems during a pelvic examination. Prior to any procedure, discussing what is involved is essential. Although this appendix will describe both a pelvic examination and a speculum examination, the midwife should remember that not all women will need a speculum examination with a pelvic examination.

During and after a pelvic examination, the choice of words and personal facial expressions should be used with intention. Helping the woman to remain calm and presenting a professional demeanor throughout are important behaviors. A woman's face usually will convey her level of comfort and sometimes if she has questions. Therefore, visualization of both faces, midwife and woman, should be unobstructed throughout the procedure. It is always preferable to have a chaperone when performing a pelvic examination regardless of gender of the provider; this person assures the woman that no untoward or unprofessional activity is likely. Pragmatically the chaperone also can hand equipment and receive specimens to facilitate the procedure.

1. Before beginning an examination, the woman should be offered the opportunity to empty her bladder.
2. It is assumed that, similar to prior to any physical examination, the midwife performs hand hygiene, preferably in front of the woman to reassure her. To minimize the risk for contamination of the room with vaginal secretions, assemble all necessary equipment prior to beginning the examination. This includes taking lids off containers and opening any packages needed.
3. When the woman is gowned for the examination, she should rest her feet in the stirrups or on the lowered section of the table and move so that her buttocks extends just beyond the end of the table. Thus, her perineum is at the edge of the table, enabling easier insertion of the speculum (**Figure 4E-1**). The woman's arms should be relaxed at her

sides or across her abdomen. Some women will be more comfortable in a semi-reclining position. The drape sheet should be adjusted as needed for modesty and some midwives advocate draping so that the woman's knees are covered and only the pelvic area uncovered.

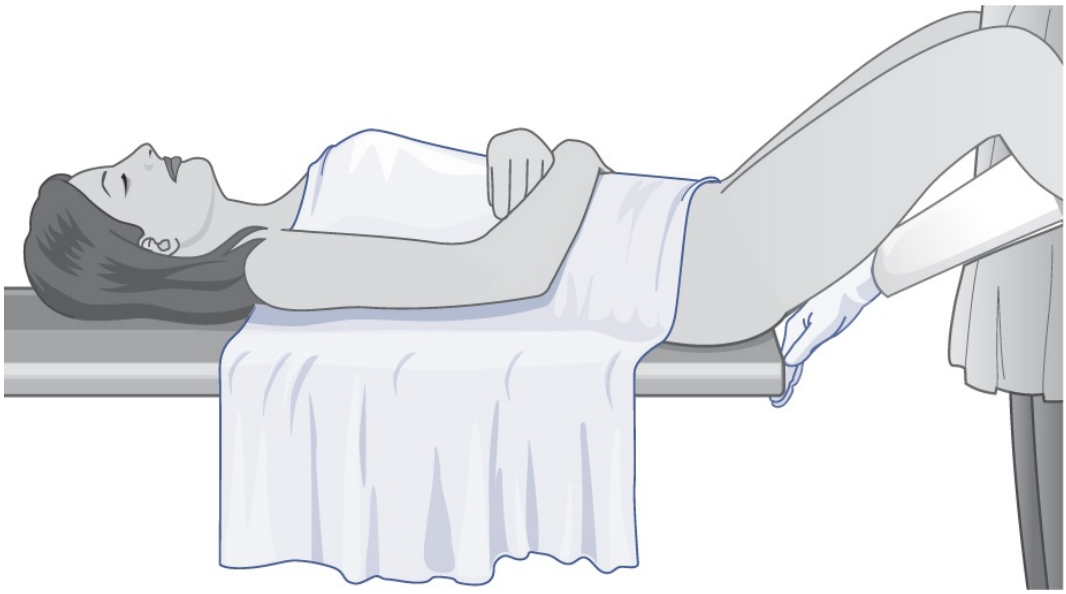

Figure 4E-1 Positioning a woman for a pelvic examination.

- **a.** Before proceeding further with the examination, as well as at any point during the procedure when the woman demonstrates potential discomfort, the midwife should verify that the woman does not feel physically uncomfortable.
- **b.** Note that this is the usual positioning for a woman in North America. In Europe, providers often examine a woman when she is in a lateral position.[1]
- **c.** Women with a physical or mental disorder may require different positioning for a pelvic examination.

4. Adjustment of the light is usually done before gloving and speculum selection. The speculum should be the correct size and mechanically functional.

- **a.** Place the speculum and any needed supplies for the examination on a clean surface. In some practices, the speculums are placed on clean areas with heating pads beneath them to warm, but not heat, the instruments.
- **b.** The means of gloving for this examination is controversial, and no single method has been demonstrated to be superior:
  - **i.** Some midwives double-glove both hands and remove the outermost glove if it touches the woman or any secretions.
  - **ii.** Others double-glove only the hand that will be used for the internal examination. The first glove is then removed after internal contact.
  - **iii.** In the past, it was common to use one glove only, which was placed on the hand that performed the internal examination. However, with the advent of universal precautions, most midwives also glove the hand that performs the

external/abdominal portion of the examination.

iv. The important factor is that the midwife continuously is aware of hand cleanliness. Cross-contamination can occur easily, especially by touching equipment, the light, or the clean area on the table after touching the woman's perineum. It is also helpful to be cautious with language and avoid using terms such as "clean" and "dirty" to designate the hand used for either equipment or direct contact with the woman. The word "dirty" as applied to the woman can be distressing if she hears it.

5. Correct choice of a speculum can both facilitate visualization and decrease the woman's discomfort. Specula come in many sizes and designs. Pederson specula are straight sided; Graves models have a "duck-billed" shape that increases visualization of the vaginal vault and fornices when lax musculature or submucosal fat impedes visualization of the upper vagina. Narrow (virginal) specula and shorter pediatric specula are also available for use whenever conditions require a smaller device. **Figure 4E-2** shows the variety of specula available. Disposable plastic specula are similar in shape to the Pederson metal specula.

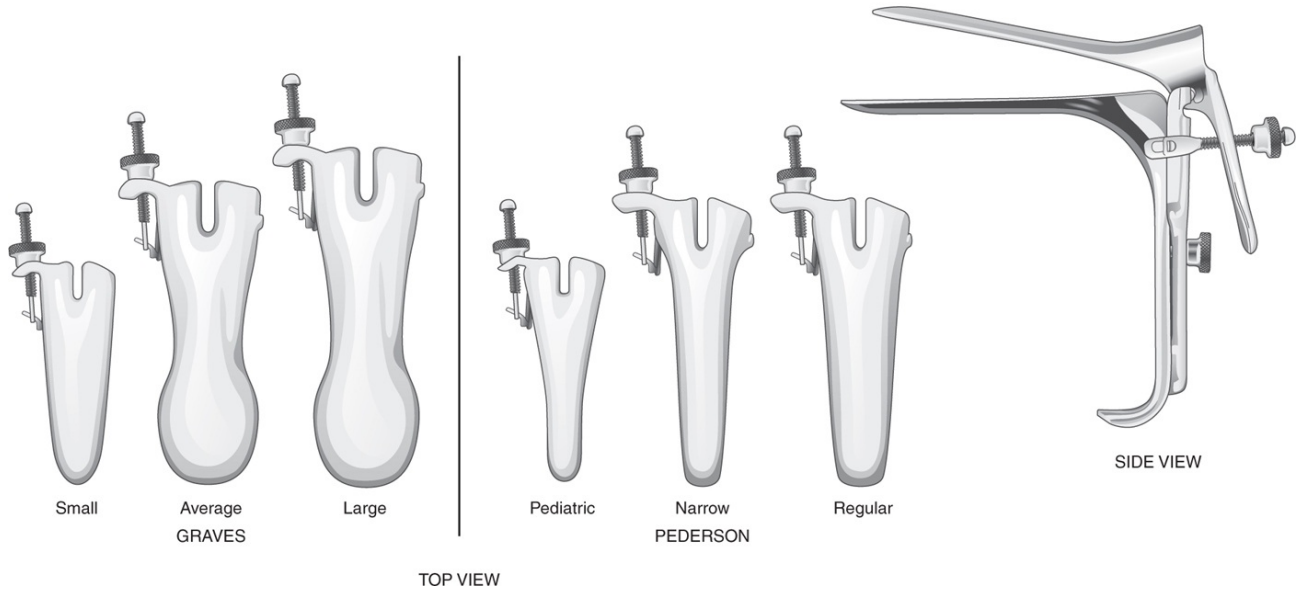

Figure 4E-2 Common vaginal speculum types.

External Inspection of the Genitalia

1. Ask the woman to allow her knees fall apart, and to relax her hip and thigh muscles.
   a. When the legs and buttocks are relaxed, there is less likelihood that the vaginal muscles will be tightened against the speculum.
   b. Remind the woman that she should speak immediately if she is having pain or desires the examination to stop.
   c. Gently touch the inside of the woman's thigh with the back of the gloved hand

intended for the internal examination before proceeding with the examination and let her know before the introitus or vagina are touched.

2. Inspect the external genitalia (**Figure 4E-3**). To do so, separate the labia majora and inspect the labia minora. Then separate the labia minora and inspect the clitoris, the inside of the labia minora, vestibule, urethral orifice, and vaginal introitus. **Table 4E-1** lists observations to be noted.

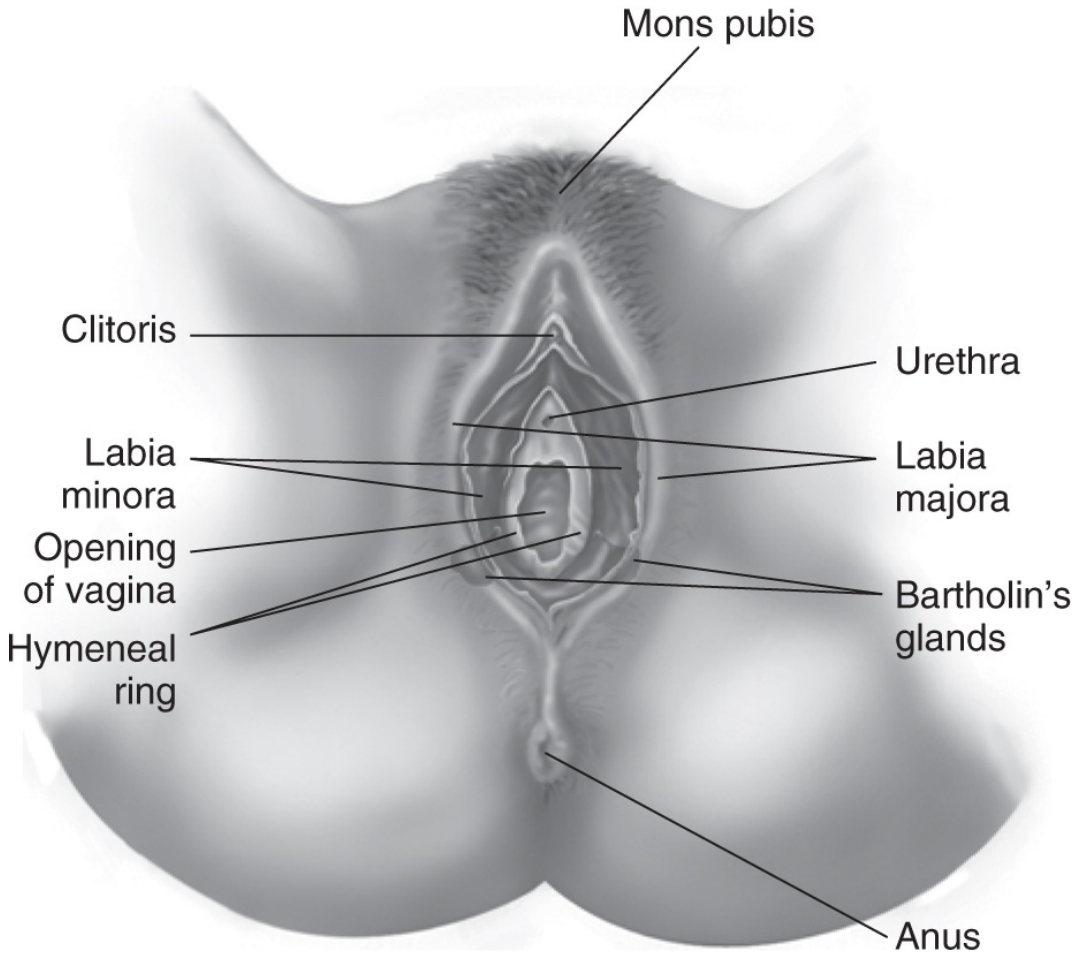

Figure 4E-3 Normal external genitalia.

Table 4E-1	Observations of the External Genitalia
During examination of the external genitalia, many observed changes provide information of clinical significance. Assess the following:	
Pattern of hair growth	Discoloration or bruising
Size and shape of each area	Cysts, polyps, condyloma, or other growths
Appearance of the introitus	Lesions, fissures, rashes, ulcerations, or crusting
Clitoral enlargement	Adhesion of tissues

Inflammation or irritation	Fistula
Swelling or edema	Uterine prolapse
Scarring	Varicosities

a. Inspect the Skene's glands and urethra for normal appearance, irritation, swelling, lesions, redness, or discharge. Separate the labia; insert one finger into the vagina, palm up; and sweep down the Skene's glands at each side of the urethra toward the introitus. Pressing directly upward onto the urethra, again sweep from the apex of the vagina toward the introitus to elicit discharge from the urethra if present.
b. Inspect the Bartholin's glands for masses, fluctuation, redness, heat, or pain, with one finger in the vagina and the other fingers and thumb outside the vagina. Palpate the entire area, usually by gently palpating the tissue between the thumb and the index finger, both sides of the vaginal opening in turn. Pay particular attention to the posterolateral portion of the labia majora.
c. Inspecting the glands before performing the speculum examination increases the likelihood that any discharge will be noted.
d. This sequence also allows for smooth transition to the speculum examination.

Speculum Examination

1. Start with use of the hand to be designated for use with equipment. Verify that the speculum previously chosen is appropriate in size and that it is warm (skin temperature). If not, discard the glove on the hand that palpated the external genitalia, correct the speculum size or temperature, and reglove.
2. If needed, lubricate the warm speculum with water, as other lubricants can interfere with specimen interpretation. Check the speculum before using it to make sure the locking knobs (metal speculum) or latch (plastic speculum) work correctly.
3. While holding the speculum by the handle and securing the two blades together with the index finger across the top blade to avoid inadvertent opening and increasing the size/diameter of the device, have the two fingers that remained in the vagina after palpation of the labia positioned in the posterior introitus (**Figure 4E-4**). If needed, the fingers may be slightly spread apart to create a visible space for insertion of the speculum.

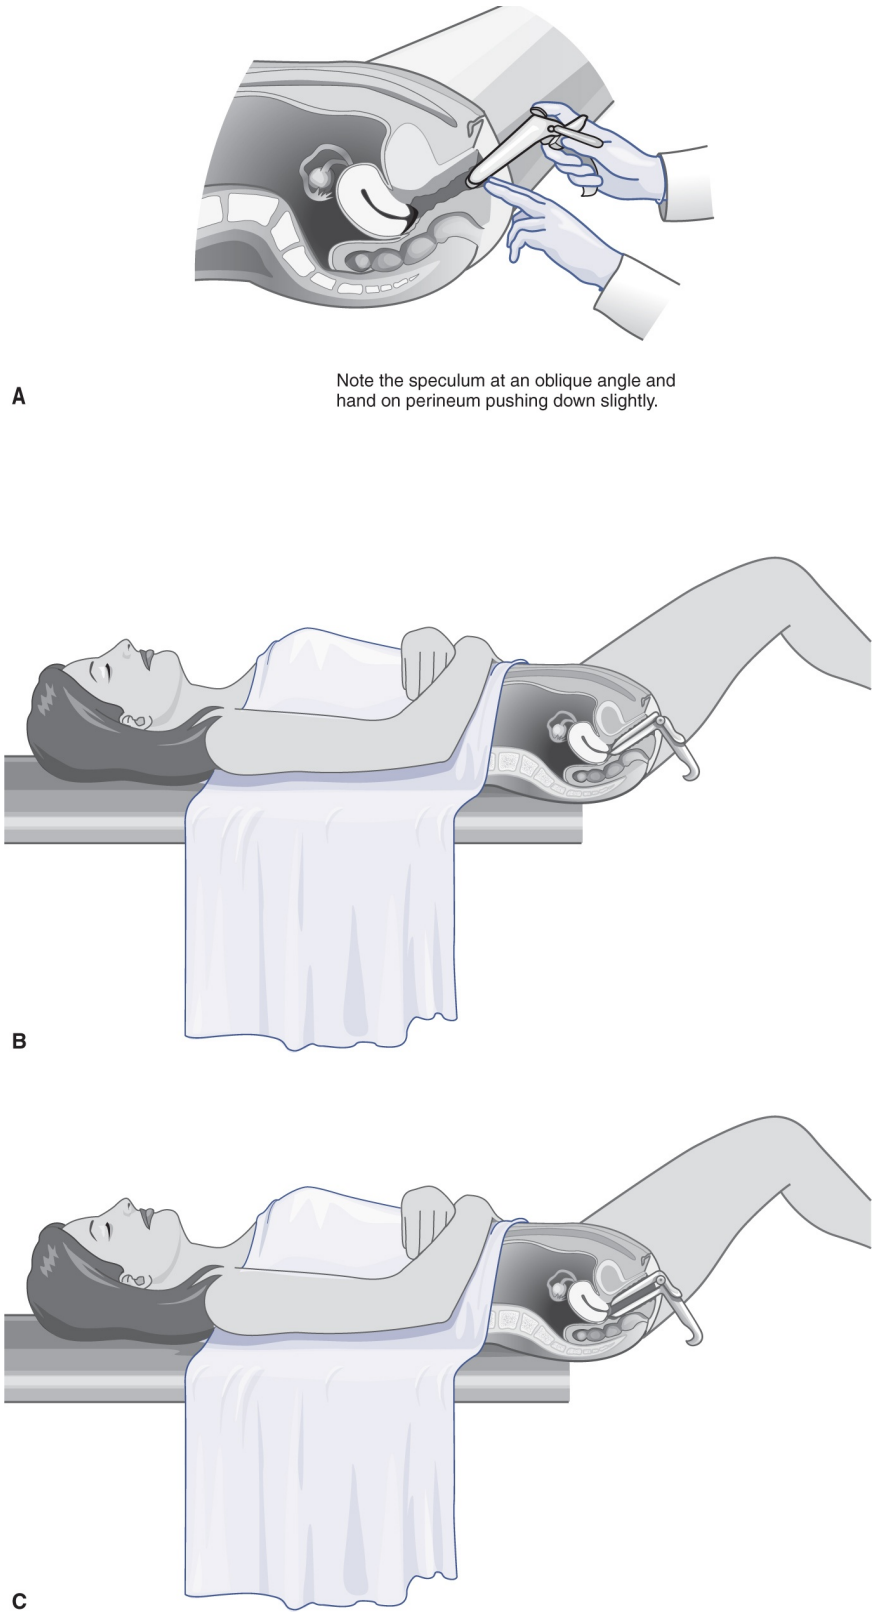

Figure 4E-4 Speculum examination. **A.** Position of the hands and speculum at insertion (speculum at oblique angle). **B.** Speculum inserted along the posterior wall of the vagina. **C.** Speculum open to visualize cervix.

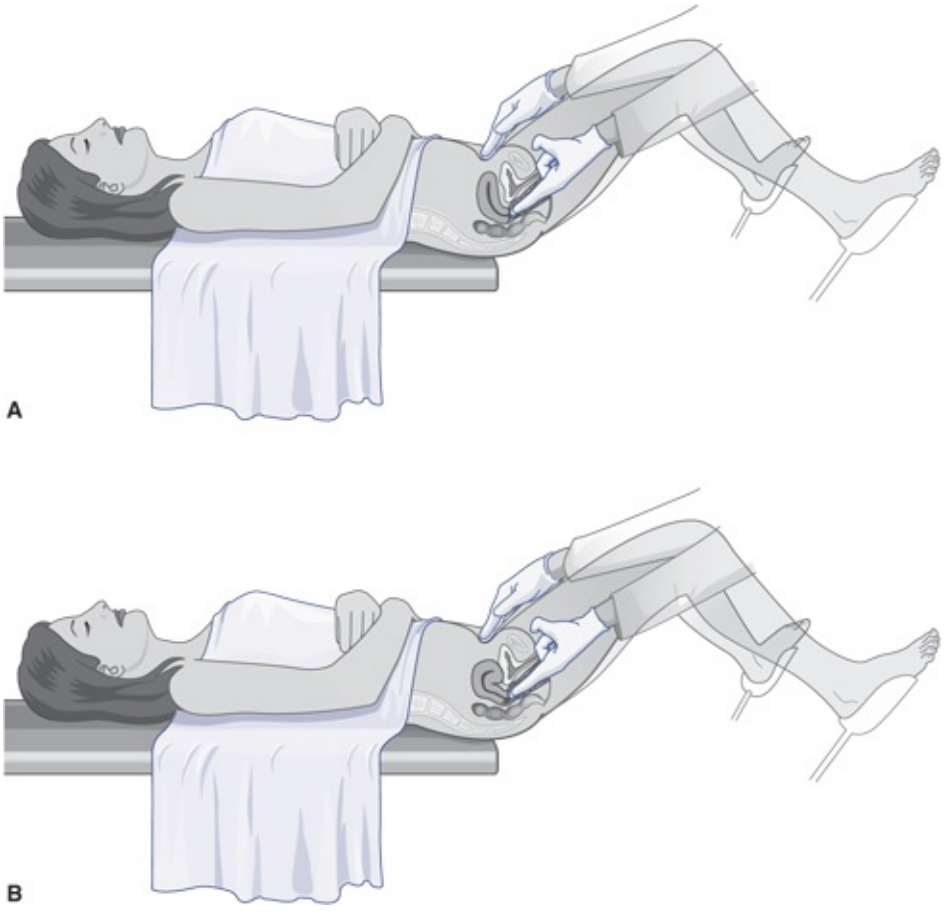
Modified with permission from Schuiling KD, Likis FE, eds. *Women's gynecologic health.* 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2017.[2]



4. Provide gentle downward pressure with the two fingers and guide the speculum blades between the two fingers into the vagina. The speculum should enter and be removed from the vagina at a 45-degree angle so the speculum avoids touching the sensitive anterior structures (e.g., urethra, clitoris). As the speculum enters the vagina, at a 45-degree angle, slowly begin to remove the fingers as the speculum slides downward along the posterior vaginal wall.
5. Rotate the speculum to a horizontal position as it moves toward the posterior portion of the vagina. Do not open the bills until the speculum is fully inserted.
6. Maintaining downward pressure, withdraw the speculum slightly and open it only as much as is needed to visualize the cervix using the thumb piece.
    a. The most common cervical position is tilted slightly posterior, so placing the speculum behind the cervix and gently opening it is the technique most likely to identify the cervix with minimal discomfort for the woman.
7. When the cervix is visible, insert the speculum slightly deeper to stabilize and improve visibility, and then use the screws or latch (on a plastic speculum) to fix the open position of the speculum. The anterior blade of a metal speculum can be adjusted if a larger area needs to be created.
    a. Note any discharge, cysts, polyps, lesions or masses, vascularity, erosion, or eversion.
8. It is at this point that specimens are collected if needed.

After collecting specimens, rotate the speculum to visualize the anterior and posterior walls of the vagina. Many midwives will perform this inspection as they slowly remove the speculum. Note that the speculum blades can be allowed to fall together after clearing the cervix. The speculum should be rotated back at a 45-degree angle as it nears the vaginal introitus and then gently removed. The woman may give a gentle push that is unnecessary, but may make her feel more in control.

Bimanual Examination

1. If necessary, discard gloves and don a new one/pair. Apply water-based gel to the fingers of the gloved hand that will be inserted into the vagina.
2. This portion of the examination is performed with two fingers in the vagina, unless the introitus is too tight or the woman too uncomfortable to tolerate more than one finger.
    a. Keep the thumb of the examining hand tucked to one side or folded into the palm to avoid unintentional pressure on the clitoris and to allow the fingers to reach farther into the vagina.
3. Pressing gently downward, insert two fingers and place them along the posterior wall of the vagina.
4. Press downward firmly to open the vagina and ask the woman to bear down, observing for the bulge of a cystocele or urethrocele. Observe for uterine descent associated with prolapse.

5. Spreading the examining fingers apart, the woman should be asked to bear down a second time, and posterior bulging associated with a rectocele or enterocele is observed if present.
6. Ask the woman to tighten her vaginal muscles around the vaginal fingers.
   a. Kegel's exercises can be taught at this point.
7. Sweep the vaginal fingers around the walls to assess for masses or lesions such as cysts, polyps, or condyloma.
8. When the fingers reach the cervix, they should be moved circumferentially around the cervix.
   a. Assess for size, consistency, smoothness, shape, mobility, and dilation.
9. Move the cervix gently side to side between two fingers to assess for cervical motion tenderness.
10. Place the external hand above the symphysis and press downward and forward toward the vaginal hand with the palmar surface of the fingers. With the vaginal hand, lift upward directly against the cervix to bring the uterine fundus in contact with the hand on the abdomen. Press both hands together gently to outline an anteverted or anteflexed uterus. The uterus should move smoothly between the hands. If necessary, reposition the abdominal hand farther up the abdomen to locate the fundus.
11. Note the position of the uterus (anteverted, retroverted, anteflexed, retroflexed, midline). Also note the shape, size, consistency, mobility, tenderness, or presence of any masses.
12. If the uterus is not identified, repeat the maneuver with the vaginal fingers on either side of the cervix (**Figure 4E-5** illustrates uterine positions).

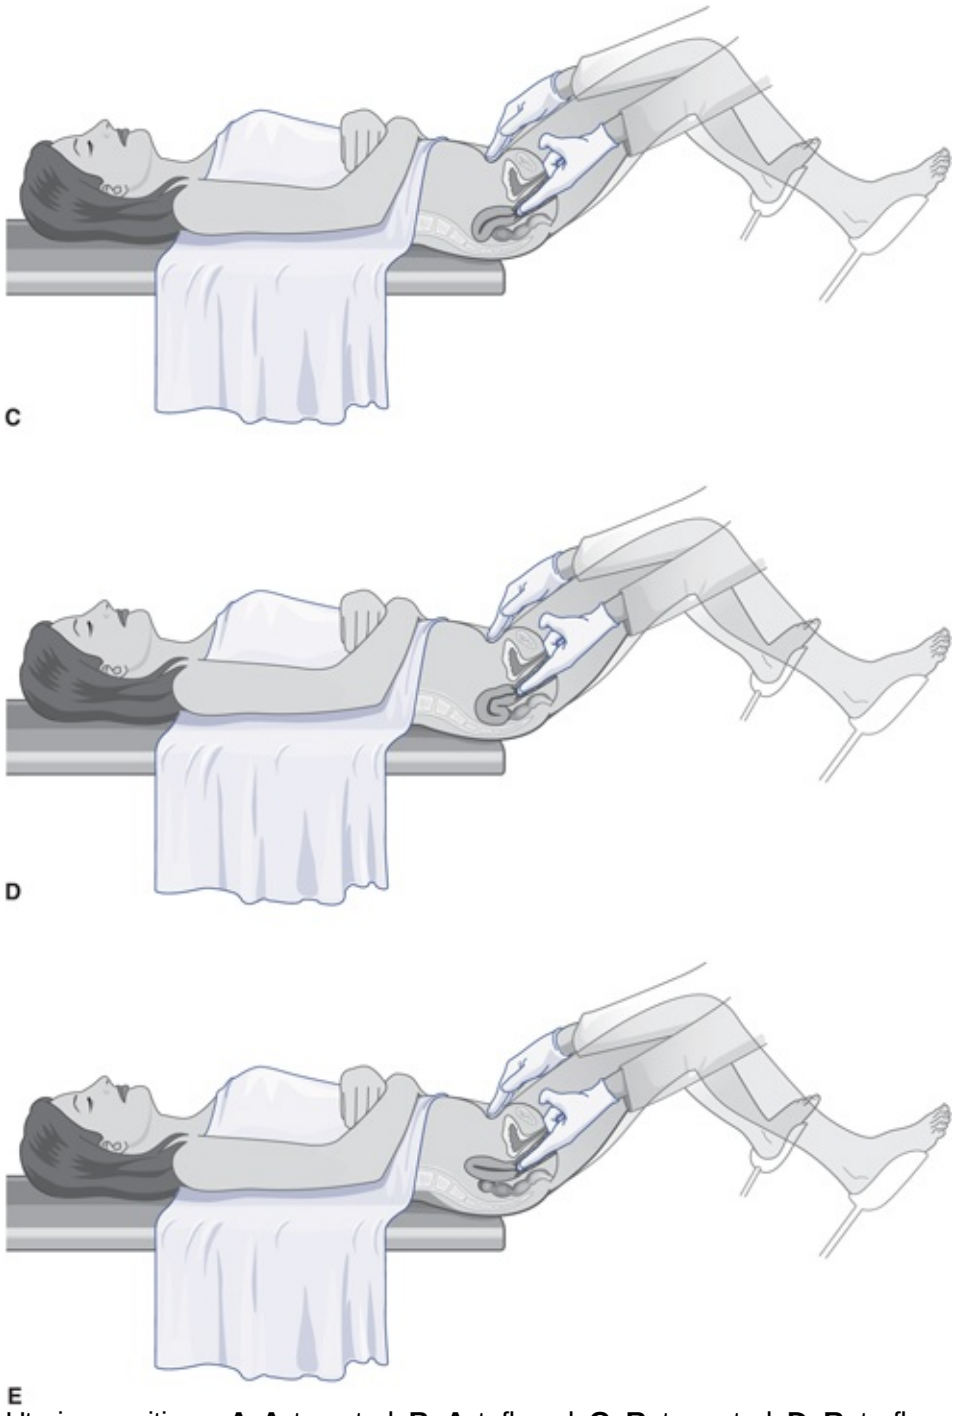


Figure 4E-5 Uterine positions. **A. A**nteverted. **B. A**nteflexed. **C. R**etroverted. **D. R**etroflexed. **E. M**idline. Modified with permission from Schuiling KD, Likis FE, eds. *Women's gynecologic health.* 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2017.[2]

13. If the uterine position is still not palpated, it may be in a midline or posterior position. With fingers in the vagina above and below the uterus, press inward with the external hand and assess as much of the lower portion of the uterus as is possible.
14. To assess the adnexa, place the external hand in the area between the iliac crest of the innominate bone and the abdominal midline midway between the level of the umbilicus and the symphysis pubis. Use the flats of the palmar surface of fingers on the abdomen to press deeply downward and obliquely toward the symphysis pubis and toward the fingers in the vagina.

15. With the internal hand in the vagina, the palm should face upward. Both of the examining fingers in the vagina are placed in the lateral vaginal fornix corresponding to the side (right or left) that the abdominal hand is positioned to examine. Press the fingers deeply inward and upward toward the abdominal hand as far as possible.
16. Palpate the entire area between the uterus and the pelvic sidewalls with a sliding, gentle, but firm touch, pressing the internal and abdominal hands toward each other as they synchronously move together from the abdominal area above the pelvic brim downward toward the symphysis.

Rectovaginal Examination

1. Not all regular examinations include a rectovaginal examination. Before attempting a rectovaginal examination, the midwife should explain why the examination is indicated —to further evaluate the uterus and adnexa or to check for fistula. Offer reassurance that if the woman can relax, the examination should not be painful.
2. Change current gloves and lubricate the examining fingers.
3. Insert a gloved index finger into the woman's vagina. Ask the woman to bear down, and gently insert the middle finger into the rectum.
4. Palpate the area of the anorectal junction and just above it. Ask the woman to tighten and relax her rectal sphincter.
   a. This position allows for assessment of sphincter tone and for internal hemorrhoids.
5. As both vaginal and rectal examining fingers slide as far as they will reach, palpate half of the rectal wall, sweeping the examining finger back and forth as the distance is covered methodically. Asking the woman to bear down extends the area that can be reached and makes the procedure more comfortable for her.
6. When a uterus is retroverted or retroflexed, the posterior side of the uterus may be palpated. Palpate as much of the posterior side of the uterus as possible with the rectal examining finger.
7. As the vaginal and rectal fingers are withdrawn, the other half of the rectal wall is examined as in step 5.
8. Remove gloves and discard them. Perform hand hygiene.
9. Assist the woman to a sitting position and offer her cleansing wipes and tissues with which to clean herself.

APPENDIX

4F

Collecting Urinary, Vaginal, Cervical, and Rectal Specimens for Testing and Interpretation of Saline and KOH Slides

JAN M. KRIEBS

© hakkiarslan/iStock/Getty Images Plus/Getty

Specimens collected during pelvic examinations are used to test for infections, risk of preterm labor, rupture of the membranes, and cervical cancer. In all cases, standard precautions are used to prevent provider exposure to blood and body fluids.[1] The order of specimen collection is determined by the purpose and type of specimen collected.

General Principles for Specimen Collection

1. Cross-contamination should be carefully avoided—either of the equipment and supplies or of the woman and clinical specimens—by the appropriate use of gloves and clean or sterile technique, and by attention to surroundings.
2. Avoiding the use of gel when collecting these specimens improves detection. The gel can interfere with testing by obscuring the collection site, altering the pH of a specimen, and making microscopy less accurate. Only warm water should be used to moisten a speculum.
3. The usual order of specimen collection is as follows:
   a. Voided urine
   b. Vaginal swab for culture/nucleic acid amplification tests (NAATs)
   c. Vaginal swab for pH, saline, or KOH
   d. Endocervical swab for NAAT or culture
   e. Papanicolaou (Pap) testing

Procedure for Collecting Urine Specimens

Urine specimens can be used for urinalysis, urine culture, and NAAT for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.

1. Determine whether a catheterized specimen is necessary before collecting the specimen. Examples of times when this might be necessary are after rupture of the membranes, during the early postpartum period, when it will be difficult for the woman to adequately clean the area, or whenever a definitive measurement of urinary protein, leukocytes, or erythrocytes is necessary.
2. If performing a bladder catheter collection:
   a. Open the sterile catheter and leave it in the sterile wrap.
   b. Don sterile gloves.
   c. Place the end of the catheter where the urine will come out into a sterile collection device.
   d. Holding the labia away from the urethra, cleanse the periurethral and vaginal area with soap (not disinfectant, which may interfere with culture). Wipe from front to back, and repeat twice, using a clean pad each time.
   e. Using aseptic technique, insert the catheter tipped with water-based lubricant into the urethra until urine is returned (usually 4–5 cm).
   f. Remove the catheter from the urethra when an adequate specimen is obtained or when urine no longer drains, depending on the purpose of the procedure.
   g. Cap the sterile collection device without contaminating the inside by touching it.
   h. Remove gloves.
   i. Label the sterile collection device.`

Procedure for Collecting and Interpreting Saline and Potassium Hydroxide Specimens for Vaginal Infections[1,2]

In the United States, microscopy for the diagnosis of infection or rupture of the amniotic membranes falls under the Clinical Laboratory Improvement Amendments of 1988 (CLIA). These federal regulations, which mandate improved quality controls, include requirements for competence in provider-performed microscopy. The Centers for Medicare and Medicaid Services is responsible for these regulations, which are published online through the CDC.[3] As with any procedure that has the potential for exposure to blood or other body fluids, standard precautions are always observed. The first step is knowing how to use the microscope (**Table 4F-1**).

Table 4F-1	Use of the Optical Microscope

An optical microscope can be used to facilitate diagnosis in the clinical setting.

Proper microscope maintenance—minimizing exposure to dust by covering the microscope when not in use, cleaning the eyepiece and objective lenses with compressed air and a lint-free paper wipe, and wiping down mechanical components with a microfiber or other lint-free cloth—will preserve the quality of images.

Prior to using a microscope for the first time, familiarity with the light source, adjustment of the fine- and coarse-focus knobs, technique for moving the slide on the mount, and the powers available for viewing a specimen is necessary.

Most modern microscopes will have a 10× eyepiece lens and 4×, 10×, and 40× objective lenses. The oil immersion lens is not used for these procedures.

Saline specimens are used for the direct visualization of vaginal yeasts, trichomonads, and clue cells typical of bacterial vaginosis. Assessment of the presence or absence of lactobacilli and white blood cells can also aid diagnosis.

A sample placed in potassium hydroxide (KOH) is used to visualize yeasts. The KOH destroys the cell walls of bacteria and epithelial cells, but not the cell walls of fungi. KOH can also be collected for use in the "whiff" test, to identify release of amines when a bacterial vaginosis specimen is exposed to an alkaline solution that also releases a strong odor.

1. Obtain dropper bottles of normal saline and KOH. Saline is preferred over distilled water to help preserve the living specimen long enough for examination.
2. Insert a moistened speculum into the vagina and visualize the cervix.
3. As the speculum is inserted and positioned, note the appearance of the perineum, vaginal mucosa, cervical epithelium, and any discharge. The discharge is categorized by quantity, color, consistency, and odor.
4. Using a sterile cotton swab, collect a sample of fluid from the posterior fornix and/or from the vaginal wall. If necessary, a second swab may be used to obtain an adequate sample.
5. Gently roll the swab across a glass microscope slide. Repeat the smear on a second slide. The specimen smear should be thin, not clumpy.
6. If gloves are contaminated, don a new set of nonsterile gloves. Place a single drop of saline onto the sample on the slide.
7. Place a single drop of KOH solution onto the sample on a second slide. It is preferable to use a second slide when collecting a sample for KOH, to prevent mixing with the saline specimen.
8. Place a cover slip over each specimen. Hold the cover slip by the edges. The cover slip should be placed at a 45-degree angle and lowered slowly, to minimize air bubbles (**Figure 4F-1**).

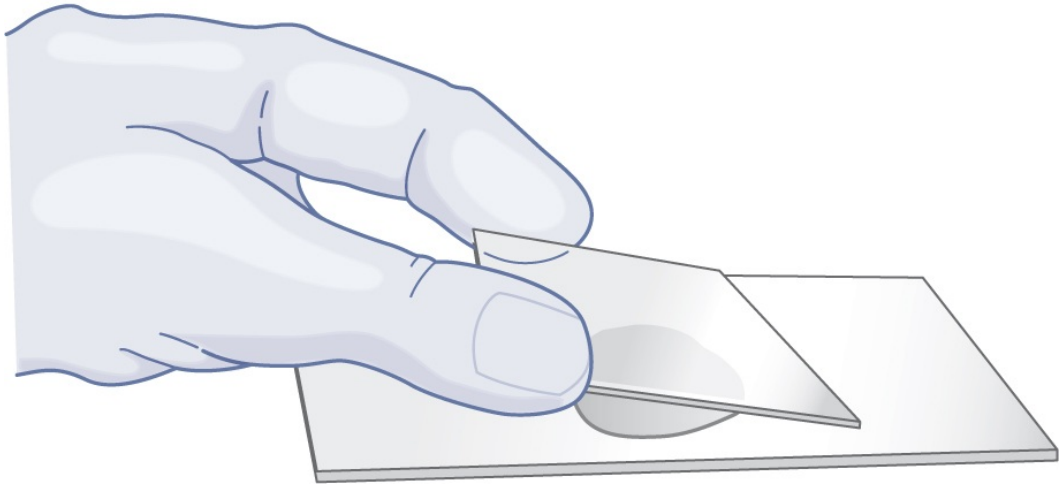

Figure 4F-1 Cover slide placement.

9. If the cover slip is floating because the specimen is too thick, a small piece of lint-free paper can be used to absorb some of the excess fluid. Place the edge of the paper at the edge of the cover slip, and allow the paper to wick away excess fluid.
10. The saline slide is inspected first, followed by the KOH slide if needed. If slides are not labeled, the difference between the two can be seen. Cells are visible on the saline slide, whereas a KOH slide looks empty or has remnants of epithelial walls. Yeast hyphae remain visible after KOH application.
11. Focus on the edge of the cover slip using the low-power lens (10×). At this point, the fine adjustment should be all that is necessary to bring specimens into focus. Fingerprints, lint, and dust can be misidentified as part of the specimen. Keeping the slide as clean as possible and carefully focusing on the edge of the cover slide will assist in finding the correct viewing plane.
12. Examine the specimen by moving the slide back and forth, using the knob or handle provided for that purpose. Enough of the slide should be inspected to provide a correct diagnosis. The entire specimen may need to be viewed because the specimen will not be distributed equally across the slide.
13. Specimens of vaginal secretions are inspected under 40× power. The samples are read as positive or negative, with details of the specific findings as needed. While the 10× lens gives an overview of cells and fungal material present, the 40× lens enables the examiner to identify blood cells, clue cells, bacteria, trichomonads, and yeast hyphae or spores accurately (**Figure 4F-2**). A more detailed discussion is found in the *Reproductive Tract and Sexually Transmitted Infections* chapter regarding the diagnosis of vaginal infections and STIs.

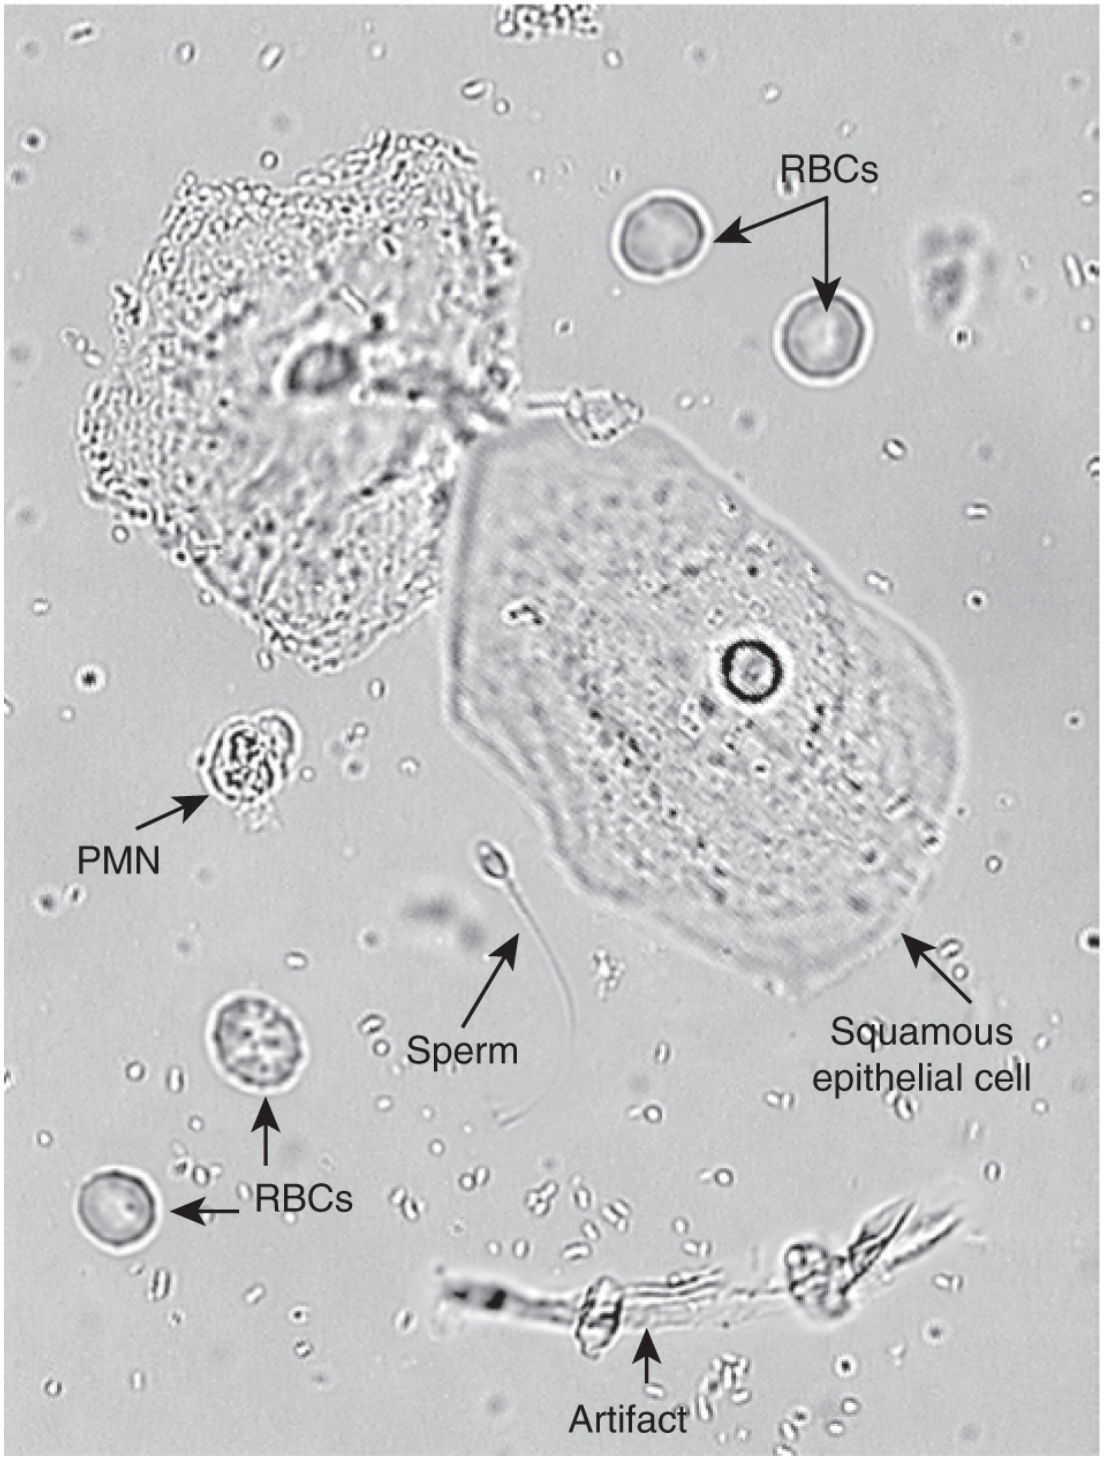

Figure 4F-2 Vaginal slide prepared with saline.

Abbreviations: PMN, polymorphonuclear; RBCs, red blood cells.

Available at: https://www2a.cdc.gov/stdtraining/ready-to-use/Manuals/Vaginitis/vaginitis-slides-2013.pptx. Accessed April 1, 2017.[4] Used with permission from Seattle STD/HIV Prevention Training Center and Cindy Fennell, MS, MT, ASCP.

14. Use the knob to move the stage away from the optic so as to minimize the risk of scratching the lens. Turn off the microscope light, clean up any spilled material, and

properly discard the sample to complete the procedure.

Procedure for Collecting Vaginal or Cervical Specimens For *N. gonorrhoeae* and *C. trachomatis*

Most laboratories now use NAAT or similar DNA-based testing for evaluation of mucopurulent cervicitis and for screening for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infection.[5,6] These tests are the most sensitive available, and their specificity is similar to that of culture. If the product being used is approved for vaginal testing, these specimens are as accurate as cervical ones, and more accurate than urine specimens in women. A provider can collect vaginal swabs, or such samples may be self-collected by the woman. Culture for *N. gonorrhoeae* is utilized as an alternative when these tests are not available or when resistance testing is needed. *Chlamydia* cultures have poor sensitivity and specificity.

1. Insert a moistened speculum into the vagina and visualize the cervix.
2. Note the presence of any discharge or cervical irritation.
3. For a vaginal specimen, swab the upper vaginal wall and posterior fornix for 10–30 seconds with a Dacron swab.
4. For cervical specimens, first use a large swab to remove any mucus discharge obscuring the cervical opening.
5. Insert a sterile Dacron swab into the cervix approximately 2 cm and rotate for 5 seconds. The specimen collected for liquid cytology Papanicolaou tests is adequate for this purpose allowing the single specimen to be used for Pap, chlamydia, and gonorrhea testing.
6. Do not allow a cervical swab to touch the vaginal walls while it is being removed.
7. Place the specimen in the transport medium.

Procedure for Performing a Papanicolaou Test

Liquid-based specimen collection, in which the specimen is collected at the cervix, has become the standard where available, due to improved ability to interpret abnormalities. This material can also be used for human papillomavirus (HPV) testing.[7] In a conventional Papanicolaou (Pap) test, a slide is made directly from the specimen collected at the cervix. An extended-tip spatula plus endocervical brush technique or broom plus endocervical brush has been shown to provide the most accurate results, and should be used whenever available,[8-10] A discussion of frequency of cervical cancer testing can be found in the *Health Promotion and Health Maintenance* chapter.

1. Insert a moistened speculum into the vagina and visualize the cervix.
2. If only a Pap test is being performed, a small amount of water-based gel can be used to lubricate the speculum.

3. Using a spatula or broom, sweep the cervix, rotating the spatula or broom 360 degrees to cover the entire ectocervix. An extended-tip spatula is the preferred device. If the squamocolumnar junction is visible, it should be included.
4. Remove the device without touching the vaginal sidewalls; rotate it gently in liquid medium to dislodge the cells, or roll it across a clean slide, depending on whether a liquid or dry collection method is used.
5. For dry specimens only: Place one flat side on the top half of the slide and stroke once to the end of the slide. Then turn the spatula or brush over and place the other flat side on the bottom half of the slide and stroke once to the end of the slide. If the specimen is too thick, take the edge of the device and, with a single light stroke down the slide, remove the excess.
6. Insert a cervical brush into the endocervix approximately 2 cm and rotate through 90 to 180 degrees.
7. Repeat the procedure for processing as in steps 4 and 5.
8. If a dry technique is used, the specimen should immediately be fixed before transport to preserve cellular integrity.

Introduction

Health promotion is the process of enabling individuals to increase control over and improve their health. Providing a person with the tools necessary to maintain optimal health is the essence of health promotion, and is done primarily through counseling, education, and shared decision making within a therapeutic relationship. Maintaining optimal health also requires the conduct of specific screening at various intervals throughout life to ensure early detection of the onset of disease states. This chapter provides information about primary and secondary health promotion and disease prevention services that aid in promoting and maintaining health for women across the lifespan. Reproductive life planning includes both primary and secondary prevention strategies and, therefore, is included in a final section. Education and counseling that are recommended for a preconception care visit are reviewed in **Appendix 5A**.

The Midwife's Role in Health Promotion

Health promotion is an essential component of midwifery practice. The International Confederation of Midwives' (ICM) *International Definition of the Midwife* articulates the key role that midwives play in health education and counseling for women, their families, and the community.[1] Similarly, the American College of Nurse-Midwives (ACNM) has identified that wellness counseling, health promotion, and disease prevention are part of the scope of practice of certified nurse-midwives (CNMs) and certified midwives (CMs).[2] Both ACNM and ICM address elements of health promotion and disease prevention in their essential/core competencies for entry-level midwifery practice,[3,4] and ACNM recognizes health promotion, disease prevention, and health education as hallmarks of the art and science of midwifery.[3]

One of the roles of the midwife is to help individuals in becoming empowered to be active participants in maintaining their health.[3,4] Furthermore, aiding women to become empowered to maintain their health and the health of their families, within the context of the communities in which women live, requires that midwives remain aware of the health status of the communities and advocate for policies that promote healthy communities.

Definition of Terms

Participating in health promotion and health maintenance first requires an understanding of key concepts and terms.

Health is defined in a number of ways, based largely on the context in which it is used. The World Health Organization (WHO) defines *health* as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."[5] The Centers for Disease Control and Prevention (CDC) defines *health* as "a human condition with physical, social, and psychological dimensions, each characterized on a continuum with positive and negative poles. Positive health is associated with a capacity to enjoy life and withstand challenges; it is not merely the absence of disease. Negative health is associated with illness, and in the extreme, with premature death."[6] If health is conceptualized as occurring along a continuum, the goal of the midwife in health promotion is to identify each individual's health

status and provide the preventive services necessary to keep that status moving in a positive direction.

Disease, for the purpose of this chapter, is defined as any disruption in the physical, emotional, or social functioning of a human being that interferes with that person's capacity to maintain optimal physical, emotional, or social health.

Primary prevention refers to the delivery of healthcare services that focus on preventing disease from occurring in a given population and in individuals.[7] Examples of primary preventive services include immunizations, counseling, and education. At the population/community level, primary preventive services include the implementation of policies that promote clean air, clean water, and workplace safety.

Secondary prevention refers to the delivery of healthcare services aimed at early detection of disease states as well as interventions that limit severity and resulting morbidity.[7] Identification of risk factors through a thorough health history and the conduct of regular screening tests at appropriate intervals in a woman's life are perhaps the most powerful secondary preventive services provided by midwives.

Tertiary prevention refers to the delivery of healthcare services that restore optimal function, improve health status, and limit long-term disability following the identification of disease.[7] Although midwives are involved in the delivery of tertiary preventive services (the treatment of women with diseases), this chapter focuses on the midwife's role in the provision of primary and secondary preventive services for individual women. Delivery of tertiary preventive services is addressed in other chapters throughout this text.

Screen is a term that can be used as a noun or a verb. As a verb, midwives screen women for certain disease states as a component of secondary prevention. As a noun, it is the screen that is evaluated during testing. Readers will see mention of screening tests and diagnostic tests throughout this text. In general, *screening tests* are laboratory (or other) tests conducted on asymptomatic, healthy women for the purpose of early detection of health problems. *Diagnostic tests* are laboratory (or other) tests conducted to confirm a diagnosis, often following a positive screen.

Health Promotion: Primary Prevention

Preventing the onset of chronic disease through primary preventive strategies is the leading goal of health promotion. The United States spends more money on health care than any country in the world.[8] In 2015, an average of $9990 per person was spent on health care, representing approximately 18% of the U.S. gross domestic product.[9] Despite the fact that healthcare spending in the United States far exceeds that of other nations, the United States has poorer health outcomes on most measures than any other developed nation.[8] Reasons for the rapid growth in U.S. healthcare spending are multifaceted, although research suggests that the costs associated with the treatment of individuals with chronic diseases are a key contributor.[8-10]

The causes of poor health outcomes in the United States are equally complex. Public health leaders have identified the lack of attention paid to health promotion as a primary contributor.[8,9] Chronic diseases, many of which are preventable, are currently the leading cause of death and disability for adults in the United States. An estimated 50% of adults living in the United States have one or more chronic health problem.[11] Rising rates of chronic disease include conditions that are largely consequences of modifiable health risk behaviors such as poor nutrition and sedentary lifestyle.[11] Associated conditions such as type 2 diabetes, hypertension, and heart disease place a financial burden on healthcare delivery systems and increase the risk of decreased quality of life and premature death for the individual.[8-11] A substantial body of evidence demonstrates that increasing preventive health services to improve population health can lead to reduced healthcare spending,[8,9] increased productivity, and improvements in quality of life.[8-11]

Education and Counseling

The leading causes of death in women—which include heart disease, cancer, stroke, chronic respiratory disease, and diabetes[12]—are strongly associated with lifestyle-related behaviors. In turn, modifying behaviors such as inactivity, poor dietary habits, and tobacco use can often reduce a woman's risk for disease-related morbidity and early death. To achieve this goal, midwives and other healthcare providers use counseling and education aimed at improving personal health practices as tools for health promotion.[13] It is important to implement these interventions in such a way that the counseling and education are meaningful to each individual.[14] An individualized education and counseling plan is based primarily on the findings of a thorough health history and physical examination during which the midwife identifies the health risks that need to be addressed.

Learning Theory

Most persons are unlikely to benefit from provider-driven teaching, in which the midwife decides what the individual needs to know and when that person needs the information. Instead, all persons are more likely to understand and implement the information provided during a teaching/counseling session when the learning is person centered—in other words,

when that person has identified a need to know and demonstrates a readiness to learn, and when the learning builds on prior experience(s).

The principles of adult learning provide a framework within which health education can be customized to meet each woman's needs. The primary goal of adult learners is to acquire skills and resources that can be applied in their daily lives, rather than simply to acquire information. Adolescents who have begun to take responsibility for making their lifestyle decisions will also benefit from the self-directed learning that may be facilitated using the principles of adult learning, as summarized in **Table 5-1**.[15] For adults, learning is a process for which the "teacher" becomes a facilitator.

Table 5-1	**Principles of Adult Learning Theory**
Adults need to know why they need to learn something before learning it.	
The self-concept of adults is heavily dependent upon a move toward self-direction.	
Prior experiences of the learner provide a rich resource for learning.	
Adults typically become ready to learn when they experience a need to cope with a life situation or perform a task.	
Adults' orientation to learning is life centered; education is a process of developing increased competency levels to achieve their full potential.	
The motivation for adult learners is internal rather than external.	

Based on Knowles MS, Holton EF, Swanson RA. *The Adult Learner: The Definitive Classic in Adult Education and Human Resource Development.* 8th ed. New York, NY: Routledge; 2015.[15]

Recognizing the external motivators for adult learners is an important first step in establishing a health promotion plan. By investigating *why* the person wants to change behavior —that is, what she or he deems to be the benefit of behavior change—the midwife gains valuable insight into *which types* of interventions will be most effective in helping someone achieve their goals. The person's talents and skills, combined with their existing beliefs, can be incorporated into the approach used to achieve behavior change. For example, when establishing a plan to increase physical activity, it is important to understand that adolescents may be interested in skill acquisition, helping others, making friends, or physical appearance. Women of all ages may view physical activity as an outlet for stress; as a way to lose weight, prevent weight gain, and tone muscles; as a way to maintain or increase physical strength; as a means by which to meet new friends; or as the best prevention for diseases such as diabetes or hypertension. Within the parameters of these motivations, the midwife can work with each individual to identify types of exercise or activity that are likely to be incorporated into that person's life.

An important component of any teaching and counseling plan is the provision of anticipatory guidance. The advent of the Internet and today's ready access to multiple sources of health information have led to a wide range of personal knowledge about health. Some individuals will be well informed but others do not have access to health information. It is, therefore, incumbent upon the midwife to anticipate the healthcare needs of each person (based on risk factors) and provide individualized counseling about appropriate health services across the lifespan.

Content to Address During Counseling and Education

After determining how to present the information, the next important step is to identify which content to address during a given clinical encounter. Again, using the principles of adult learning, this step is completed with the individual and the midwife acting in partnership. Women often present to a clinical encounter with specific questions for their healthcare providers. In those instances, it is easy to design a teaching plan based on the explicitly expressed needs of the woman. Whether the woman presents for a lengthy appointment for a full physical examination or for a brief appointment and targeted examination for a specific concern, it is important for the midwife to honor (and respond to) the learning needs that are identified by the woman, especially when the time spent with the woman is limited.

Time is a precious commodity in a busy practice setting. When designing a teaching/counseling plan, only information about topics for which evidence of effectiveness exists should be included. Spending time on the delivery of care or services that are not evidence based means that less time can be devoted to care and services for which there is evidence of effectiveness. Moreover, in 2003, the Institute of Medicine issued a report recommending that all health professionals be educated to deliver patient-centered care with an emphasis on evidence-based practice.[16]

Evidence-Based Counseling Interventions

For the past 2 decades, healthcare providers have been strongly encouraged to participate in evidence-based practice (EBP), referring to the delivery of evidence-based care. One of the earliest definitions of evidence-based practice was "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available clinical evidence from systematic research."[17] ACNM has recognized the importance of providing care based on scientific knowledge of best practices and defines evidence-based practice as "the integration of the best research evidence with clinical expertise and client values."[18] Values and preferences include anything that makes an individual woman unique, such as religious and cultural beliefs, literacy level, and the woman's prior experience and knowledge.

U.S. Preventive Services Task Force

Professional organizations such as the American Congress of Obstetricians and Gynecologists and the American Cancer Society have been advancing recommendations regarding preventive services for several decades. However, it was not until the 1989 publication of *Guide to Clinical Preventive Services* by the U.S. Preventive Services Task Force (USPSTF) that healthcare professionals were provided with recommendations that were based on an unbiased review of scientific evidence. The mission of the USPSTF is "to improve the health of all Americans by making evidence-based recommendations about clinical preventive services and health promotion. These recommendations, which are developed for primary care clinicians are grounded in science, include screening tests, counseling about healthful behaviors, and preventive medications."[19] The recommendations of the USPSTF are considered the "gold standard" for clinical preventive services.[19]

Adopting evidence-based practices is not always easy. One of the fundamental ethical principles upon which healthcare delivery is based is the principle of nonmaleficence, or "doing no intentional harm." Consequently, accepting new evidence that suggests a previously accepted clinical practice may be harmful can be challenging. For example, in 2009, the USPSTF published new recommendations for breast cancer screening, which included a recommendation *against* teaching women without known risk factors for breast cancer to do breast self-examination: The scientific evidence revealed moderate certainty that the harms associated with teaching breast self-examination outweigh the benefits in this population.[20] Many midwives have been teaching breast self-examination since they began clinical practice and can cite examples of women who were adamant that their lives were saved because they found a mass during self-examination. However, implementing evidence-based preventive services requires that midwives establish individualized plans for health promotion that are based on best evidence rather than what they "believe" is best practice. At best, time spent teaching breast self-examination is an inefficient use of time that could have otherwise been spent on the delivery of care that is evidence based; at worst, time spent teaching breast self-examination may actually be harmful.

To aid clinicians in selecting evidence-based approaches, the USPSTF provides recommendations for clinical preventive services, including counseling interventions. The USPSTF recommendations reflect the strength of the available evidence and the magnitude of net benefit from the intervention (i.e., benefit minus harms). Professionals may find minor differences in the grading of evidence by the USPSTF based on the year in which the recommendations were made. Recommendations from 2012 to the present (**Table 5-2**) are based on categories that were slightly modified from the pre-2007 scale.[21] Grades A and B remain interventions that should be offered to women. **Table 5-3** identifies the level of certainty regarding the net benefits associated with healthcare practices.[21] Both the grading scale and level of certainty are used to evaluate specific therapeutic interventions or techniques.

Table 5-2 **U.S. Preventive Services Task Force Grade Definitions After July 2012**

Grade	Definition	Suggestions for Practice
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service.
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service.
C	The USPSTF recommends selectively offering or providing this service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small.	Offer or provide this service for selected patients depending on individual circumstances.
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service.
I Statement	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.

Abbreviation: USPSTF, U.S. Preventive Services Task Force.

Table 5-3 **Levels of Certainty Regarding Evidence of Net Benefit**

Level of Certainty[a]	Description
High	The available evidence usually includes consistent results from well-designed, well-conducted studies in representative primary care populations. These studies assess the effects of the preventive service on health outcomes. This conclusion is therefore unlikely to be strongly affected by the results of future

	studies.
Moderate	The available evidence is sufficient to determine the effects of the preventive service on health outcomes, but confidence in the estimate is constrained by such factors as: The number, size, or quality of individual studies. Inconsistency of findings across individual studies. Limited generalizability of findings to routine primary care practice. Lack of coherence in the chain of evidence. As more information becomes available, the magnitude or direction of the observed effect could change, and this change may be large enough to alter the conclusion.
Low	The available evidence is insufficient to assess effects on health outcomes. Evidence is insufficient because of: The limited number or size of studies. Important flaws in study design or methods. Inconsistency of findings across individual studies. Gaps in the chain of evidence. Findings not generalizable to routine primary care practice. Lack of information on important health outcomes. More information may allow estimation of effects on health outcomes.

[a] The USPSTF defines certainty as "likelihood that the USPSTF assessment of the net benefit of a preventive service is correct." The net benefit is defined as benefit minus harm of the preventive service as implemented in a general, primary care population. The USPSTF assigns a certainty level based on the nature of the overall evidence available to assess the net benefit of a preventive service.

Reproduced with permission from U.S. Preventive Services Task Force. Grade definitions. 2016. Available at: https://www.uspreventiveservicestaskforce.org/Page/Name/grade-definitions. Accessed June 5, 2017.[21]

Although the USPSTF has provided many recommendations to implement preventive services that are evidence based (A and B grade services), there remain some services for which there is insufficient evidence to make a recommendation (I grade) and some services for which there is a moderate degree of certainty that the net benefit is small (C grade). Decisions to use those services are reached through shared decision making, in which the midwife and the individual decide together whether to use a given service. When these services are used, the recipient of care should be informed about the lack of available evidence (or conflicting evidence) that supports use of the service.

The USPSTF recommendations are frequently updated. As new evidence regarding preventive health services emerges, recommendations are modified to reflect the current body of evidence. Presented in this chapter are the major counseling interventions recommended by the USPSTF, at the time of this text's publication. Readers are advised to regularly review the USPSTF website for updates to these recommendations, and for the addition of new recommendations for preventive services. Links to this website are provided in the Resources section at the end of the chapter.

Behavioral Counseling Interventions

Behavioral counseling interventions include education, counseling, and other interventions provided in primary care settings that are focused on assisting individuals to adopt new behaviors, change existing behaviors that lead to poor health outcomes, and maintain behaviors

that improve health status.[22] Most of the counseling interventions that are recommended for women involve the implementation of some type of lifestyle change or avoidance of risky behaviors.

Alcohol Misuse

Alcohol is the third leading cause of preventable deaths in the United States,[23] and diseases caused by alcohol misuse, including fetal alcohol syndrome, are preventable. Risks associated with excessive alcohol use in women include liver disease, heart disease, brain damage, some forms of cancer, sexual assault, unintended pregnancy and sexually transmitted infections, accidental injury, and premature death. According to the CDC, 53.6% of nonpregnant women and 10.2% of pregnant women use alcohol.[24] An estimated 18.2% of nonpregnant women and 3.1% of pregnant women report participating in episodic (binge) drinking, which the CDC defines as the consumption of more than three alcoholic beverages on one occasion (for women).[24] For women who are not pregnant, an occasional drink is generally considered safe. However, no level of alcohol use is considered safe during pregnancy. Complete abstinence from consuming alcohol is recommended for women who are pregnant or trying to become pregnant.[24,25] For pregnant women, any consumption of alcohol may cause fetal alcohol syndrome, other disorders along the fetal alcohol spectrum, and/or other adverse fetal/neonatal outcomes.[24,25]

The USPSTF uses the term “alcohol misuse” to describe a range of behaviors that includes risky or hazardous drinking, harmful alcohol use, alcohol abuse and alcohol dependence.[24] Screening for alcohol misuse and provision of counseling interventions to reduce alcohol misuse is recommended for all adults in all primary care settings. To date, the USPSTF has found insufficient evidence to recommend for or against screening and counseling interventions for adolescents.[24]

Levels of drinking behavior are also defined by various groups or organizations. For example, the *Dietary Guidelines for Americans* (developed by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture) define moderate drinking as “up to 1 drink per day for women and up to 2 drinks per day for men.”[25] Binge drinking is defined by the National Institute on Alcohol Abuse and Alcoholism as alcohol consumption that results in a blood alcohol concentration to 0.08 g/dL, which typically happens after consumption of 5 drinks for men and 4 drinks for women over a 2-hour time period.[25]

These definitions also illustrate the difference between screening and assessment: The purpose of *screening* is to identify persons who may have a problem with alcohol misuse based on their level of drinking behavior, while the purpose of *assessment* is to identify the extent of the alcohol problem for persons who have a positive screen.[26] As primary care providers, the recommendation for midwives is to periodically screen all clients and provide a brief intervention to reduce alcohol misuse; women who continue to misuse alcohol may be alcohol dependent and may need to be referred for further assessment and treatment.[24,26]

Ideally, screening for alcohol misuse should take place in settings that allow for assessment and follow-up of persons with a positive screen. Midwives who work in settings without

resources for follow-up care will need to identify healthcare providers in the community (or surrounding area) to whom individuals with a positive screen can be referred.

Screening for alcohol misuse begins by asking the woman how much alcohol she drinks. If the woman indicates that she never consumes any alcohol, the screen is complete. Documentation in the medical record should include the finding of a negative screen for alcohol misuse and a plan to rescreen in one year. If the woman indicates that she consumes any alcohol, the screen continues using a reliable screening instrument.

The USPSTF recommends using the Alcohol Use Disorders Identification Test (AUDIT), Alcohol Use Disorders Identification Test—Consumption (AUDIT-C), or a single-question screen to assess for alcohol misuse in primary care settings.[23] The easiest of these instruments to administer is the single-question screen, in which the midwife simply asks a woman about how many times during the past year she consumed 4 or more drinks in one day; a response of one or more times in the last year is considered a positive screen and signals the need to complete the full AUDIT.[27] The full AUDIT screen is presented in **Table 5-4**.[28] The AUDIT-C (**Table 5-5**[29]) is an abbreviated version of the AUDIT and takes just 1 to 2 minutes to complete. After assuring the woman that the information she shares will remain confidential, the midwife can administer any of these instruments during the collection of a complete health history or separately for a brief assessment of alcohol misuse. As is true for the entire health history, it is important to remain nonjudgmental when asking questions about sensitive topics such as alcohol use.

Table 5-4 **The Alcohol Use Disorders Identification Test (AUDIT)**

1. How often do you have a drink containing alcohol?
   - (0) Never (Skip to Questions 9–10)
   - (1) Monthly or less
   - (2) 2 to 4 times a month
   - (3) 2 to 3 times a week
   - (4) 4 or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?
   - (0) 1 or 2
   - (1) 3 or 4
   - (2) 5 or 6
   - (3) 7, 8, or 9
   - (4) 10 or more
3. How often do you have six or more drinks on one occasion?
   - (0) Never
   - (1) Less than monthly
   - (2) Monthly
   - (3) Weekly
   - (4) Daily or almost daily
6. How often during the last year have you been unable to remember what happened the night before because you had been drinking?
   - (0) Never
   - (1) Less than monthly
   - (2) Monthly
   - (3) Weekly
   - (4) Daily or almost daily
7. How often during the last year have you needed an alcoholic drink first thing in the morning to get yourself going after a night of heavy drinking?
   - (0) Never
   - (1) Less than monthly
   - (2) Monthly
   - (3) Weekly
   - (4) Daily or almost daily
8. How often during the last year have you had a feeling of guilt or remorse after drinking?
   - (0) Never
   - (1) Less than monthly
   - (2) Monthly

4. How often during the last year have you found that you were not able to stop drinking once you had started?
   (0) Never
   (1) Less than monthly
   (2) Monthly
   (3) Weekly
   (4) Daily or almost daily
5. How often during the last year have you failed to do what was normally expected from you because of drinking?
   (0) Never
   (1) Less than monthly
   (2) Monthly
   (3) Weekly
   (4) Daily or almost daily
9. Have you or someone else been injured as a result of your drinking?
   (0) No
   (2) Yes, but not in the last year
   (4) Yes, during the last year
10. Has a relative, friend, doctor, or another health professional expressed concern about your drinking or suggested you cut down?
   (0) No
   (2) Yes, but not in the last year
   (4) Yes, during the last year

Add up the points associated with answers. A total score of 8 or more indicates harmful drinking behavior (a positive screen).

Reproduced with permission from Substance Abuse and Mental Health Services Administration, HRSA Center for Integrated Health Solutions. The Alcohol Use Disorders Identification Test (AUDIT). Available at: http://www.integration.samhsa.gov/clinical-practice/screening-tools#drugs. Accessed June 8, 2017.[28]

Table 5-5 **AUDIT-C Questionnaire**

1. How often do you have a drink containing alcohol?
   a. Never
   b. Monthly or less
   c. 2 to 4 times a month
   d. 2 to 3 times a week
   e. 4 or more times a week
2. How many standard drinks containing alcohol do you have on a typical day?
   a. 1 or 2
   b. 3 or 4
   c. 5 or 6
   d. 7 to 9
   e. 10 or more
3. How often do you have six or more drinks on one occasion?
   a. Never
   b. Less than monthly
   c. Monthly
   d. Weekly
   e. Daily or almost daily

The AUDIT-C is scored on a scale of 0–12. For each question, a = 0 points; b = 1 point; c = 2 points; d = 3 points; e = 4 points.

In women, a score of ≥ 3 is considered a positive screen.

Reproduced with permission from Substance Abuse and Mental Health Services Administration, HRSA Center for Integrated Health Solutions. AUDIT-C Overview. 2014. Available at: http://www.integration.samhsa.gov/clinical-practice/screening-tools#drugs. Accessed June 8, 2017.[29] Scoring matrix modified with permission from Substance Abuse and Mental Health Services Administration.

Most women who use alcohol do so within the limits that are considered safe. For these women, the goal of behavioral counseling is to prevent the onset of risky or hazardous drinking. Counseling should include reminders about safe use limits and recommendations for abstinence when necessary (such as when pregnant or planning a pregnancy, or when medication use or other health conditions warrant abstinence).[26] Documentation in the health record should include the finding of a negative screen for alcohol misuse and plans to rescreen in one year.

The USPSTF recommends behavioral counseling interventions for women with a positive screen for risky or hazardous drinking and referral for further assessment and treatment for women in whom alcohol abuse or dependence is suspected.[23] For women with a positive screen, several counseling interventions are available that are designed for use in primary care settings. The brief intervention recommended by the National Institute on Alcohol Abuse and Alcoholism[26] is based on the *5 A's* construct (assess, advise, agree, assist, arrange), as outlined in **Table 5-6**.[30] The same approach may also be of value when identifying the use of other substances separate from or in addition to alcohol. Additional resources for clinicians who conduct brief interventions in clinical settings are provided in the Resources section at the end of this chapter.

Table 5-6	5 A's for Alcohol Misuse

Assess or ask the person about alcohol use and desire to change behavior.

Advise the person to change risky behavior using a personalized approach that includes information about the harmful effects of alcohol use and benefits of changing behavior.

Agree upon treatment goals and approaches to changing behavior.

Assist the person in achieving agreed-upon goals by providing education, support and encouragement, and formal counseling when necessary. This may include helping the individual identify sources of social support for change.

Arrange follow-up visits for ongoing assistance with behavioral change and referral to treatment when necessary.

Note: Although these questions have been developed to conduct a brief intervention for alcohol misuse, they can be modified for use with brief interventions to aid women with other behavioral changes such as tobacco use or weight loss.

Based on Whitlock EP, Orleans CT, Pender N, Allan J. Evaluating primary care behavioral counseling interventions: an evidence-based approach. *Am J Prev Med.* 2002;22(4):267-284.[30]

Informing a woman about the finding of a positive screen and the need for referral must be done with sensitivity. The best approach is to tell the woman that her responses to the screening questions raise a concern that her alcohol use may be harmful and that she would benefit from meeting with a provider who specializes in alcohol counseling. For example, the

midwife might address the referral in the following way:

> *One of the things we know about alcohol is that it can cause serious health problems for women who drink more than what is considered safe. For women, having more than seven drinks per week or more than three drinks on one occasion is considered "risky or hazardous" drinking.*[23,26] *Based on your response to the questions I asked about alcohol use, your use of alcohol may fall into the "harmful" category. It may be that this is not the case, but just to be sure, I would like you to see one of my colleagues who is very skilled at assessing alcohol use and at helping women make changes in their alcohol use before it has a negative effect on their health.*

Documentation in the woman's health record includes the finding of a positive screen for alcohol misuse, a description of the behavioral counseling intervention that was provided and/or referrals that were made, and the plan for return visits for ongoing support.

Breastfeeding

The benefits of breastfeeding for women and infants are well documented. Although breastfeeding rates are increasing,[31] the United States has not yet met the *Healthy People 2020* goals for infant feeding, which include increasing the proportion of infants who are ever breastfed to 81.9%, the number of infants breastfed at 6 months to 60.6%, and the number of infants breastfed at 1 year to 34.1%.[32]

Interventions in primary care settings to promote breastfeeding result in increased rates of breastfeeding initiation as well as increased duration of breastfeeding. Therefore, the USPSTF recommends interventions during pregnancy and the postpartum period to promote breastfeeding and provide ongoing support for women who choose to breastfeed.[33] The most effective interventions use combined approaches to breastfeeding support, such as promoting the benefits of breastfeeding, providing practical advice and formal education for women and families, direct support, health professional training in breastfeeding support, and peer support and counseling.[33] Breastfeeding education and counseling is reviewed in the *Prenatal Care* and *Breastfeeding and the Mother–Newborn Dyad* chapters.

Dental Health

Dental health is often not considered by primary care providers, yet dental disease can have profound adverse effects on health such as increasing risk of cardiovascular disease among all individuals and increasing the risk of preterm birth for women who are pregnant. The last USPSTF recommendations for counseling interventions to prevent dental disease were established in 1996. Those recommendations were to counsel individuals to floss and brush their teeth daily with a fluoride-containing toothpaste and to regularly see a dental provider.[34] Since that time, there has been no new evidence regarding the primary provider's role in promoting oral health, so the USPSTF has elected to maintain the 1996 recommendation and

not modify it.[35] Recommendations of the CDC aimed at maintaining good oral health include drinking fluoridated water, brushing teeth with fluoridated toothpaste and flossing, visiting the dentist regularly, not using tobacco, limiting alcoholic beverages, maintaining control of diabetes and other chronic diseases, avoiding medications that cause dry mouth, and drinking plenty of water if dry mouth cannot be avoided.[36]

Dietary Counseling

The benefits of healthy eating and the risks associated with an unhealthy diet are well documented. Of the 10 leading causes of death in women, four are related to diet—namely, heart disease, certain forms of cancer, stroke, and diabetes.[12] Assessing the dietary counseling needs of individual women first requires the collection of a 24- to 48-hour recall diet history to evaluate nutritional and caloric intake, determination of height and weight for calculation of body mass index (BMI), and obtaining a health history for identification of risk factors that may be related to diet.

A BMI of less than 18.5 is considered "underweight"; a BMI in the range 18.5–24.9 is considered "normal"; a BMI in the range 25–29.9 is considered "overweight"; and a BMI of 30 or higher is considered "obese."[37] Women whose weight is categorized as underweight, overweight, or obese are at increased risk for weight-related morbidity and mortality. Poor dietary intake is a modifiable risk factor for several diseases, including certain forms of cancer and coronary artery disease. As such, improving dietary intake can result in improvements in overall health status, especially for women with additional risk factors (e.g., hypertension, dyslipidemia, impaired fasting glucose, metabolic syndrome, and family history) for diet-related diseases.[38] The USPSTF also recommends screening all women for obesity (using BMI) and offering women with a BMI of 30 or higher intensive, multicomponent behavioral interventions.[39] Intensive behavioral counseling interventions that address diet and physical activity are also recommended for adults who are overweight or obese and who have additional risk factors for cardiovascular disease.[38] The decision to offer diet counseling to women who are not obese and do not have risk factors for coronary artery disease should be made on an individual basis based on the healthcare needs of the woman.[39]

The *Nutrition* chapter contains a detailed description of dietary recommendations and healthy eating. Similar to the brief intervention for alcohol misuse, the 5 A's construct can provide a framework for behavioral counseling interventions for women who are overweight or obese.[40] The 5 A's for alcohol misuse can be modified for use with women who are overweight or obese. Midwives may also consider referral to programs or clinicians who specialize in intensive, counseling interventions.[38] Documentation in the health record should include findings of the dietary assessment, health risk assessment, BMI, and a description of the counseling and/or referral that was provided.

Genetic Assessment for Cancer Risk

Breast cancer is a leading cause of death for women in the United States. In 2014, nearly 237,000 women were diagnosed with breast cancer in the United States, and more than 41,000

women died from breast cancer in that same year.[41] The two most influential risk factors for breast cancer are gender and age; most breast cancers are discovered in women who are 50 years or older. Another important risk factor for breast cancer is a harmful mutation of the breast cancer susceptibility genes (*BRCA1* or *BRCA2*).[41] Mutations of the *BRCA1* and *BRCA2* genes are primarily associated with significant increases in risk for breast, ovarian, and fallopian tube cancers, but are also related to other forms of cancer.[42]

Collection of a complete health history should include a thorough assessment of a woman's family history, including her family's history of cancer. More specifically, a thorough family history includes identification and documentation of which family members were affected, the specific type of cancer and cancer site, age at diagnosis and gender of affected family members, and any family members with more than one type of cancer.[42] Seven findings in a family history are associated with an increased likelihood of harmful BRCA mutations. Findings associated with an increased risk for BRCA mutation include a family history of (1) breast and ovarian cancer, (2) breast cancer diagnosis prior to age 50 years, (3) bilateral breast cancer, (4) multiple cases of breast cancer in the family, (5) breast cancer in one or more male family members, (6) one or more family members with two types of BRCA-related cancer, and (7) Ashkenazi Jewish ethnicity.[42] Women whose family history includes one or more of these findings should be offered additional screening for genetic risks.

One of several familial risk stratification tools that can reliably detect women who should be offered genetic counseling can be used.[42] Previously validated screening tools include the Ontario Family History Assessment Tool, Manchester Scoring System, Referral Screening Tool, Pedigree Assessment Tool, and the Family History Screen—7 (FHS-7). The easiest of these instruments to use in primary care settings are the Referral Screening Tool and the FHS-7.[42] Both tools can be found online, and the links are included in the Resources section at the end of this chapter. The USPSTF further recommends that women with a positive screen be referred to a healthcare provider who is trained to conduct genetic counseling for additional assessment and counseling and genetic testing if indicated and if the woman choses to obtain genetic testing.[42]

Midwives can initiate the process of screening and counseling as part of the well-women history and physical examination. Counseling should include reassurance that the findings of the health history provide a basic screen for cancer risk, and that although most women have one or more risk factors, most women do not develop cancer.[41] Documentation in the health record should include findings related to the family history and, if used, findings from the validated screening tool as well as a description of the counseling and referral that was provided for women with a positive screen. A detailed discussion about BRCA screening can be found in the *Breast Conditions* chapter.

One of the challenges in the many steps of screening and counseling about BRCA-related mutations can be the (lack of) availability of trained genetic counselors. Furthermore, even when genetic counseling is available, this service may not be covered by insurance and may present a significant cost for women whose initial screening indicates the need for referral. Midwives are advised to familiarize themselves with the availability and costs associated with genetic counseling services. These services include those available in the woman's

community and surrounding areas as well as genetic counseling services available by telephone and online, which are recommended for women who would otherwise lack access to genetic counseling services.[42] A link to genetic counseling resources can be found in the Resources list at the end of this chapter.

Injury Prevention

Unintentional injury is the sixth leading cause of death in women in the United States.[12] Injuries related to motor vehicle crashes are the leading cause of death for individuals age 1–54 years.[43] Although such injuries are usually related to accidents and, therefore, are difficult to control, the USPSTF recognizes several interventions that can effectively limit the risk for unintentional injury. There is insufficient evidence to assess the balance of benefits and harms of counseling individuals about proper use of seat belts and child safety seats, however.[43]

One reason for this equivocation is that legislative action and community-based intervention, combined with counseling in the primary care setting, have already led to substantial increases in the number of persons in the United States who properly use motor vehicle restraints.[44] Approximately 87% of front-seat occupants now use seat belts, and the rate of seat belt use for rear-seat occupants is estimated at 78%.[44] Whether regularly counseling women in primary care settings would increase proper use rates even further is largely unknown. Nevertheless, the USPSTF and the CDC recognize that harms from counseling about proper motor vehicle safety restraints are minimal to absent.[45]

Improved seat belt use and reduced rates of alcohol-impaired driving would likely have the greatest effect in lowering rates of motor vehicle fatalities.[44] Therefore, counseling women to use motor vehicle restraints properly is likely to cause no harm and may lead to further reductions in motor vehicle–related injury and death. The CDC recommends that healthcare providers counsel parents and caregivers of children about the importance of using age- and weight-appropriate car seats and restraints at all times. The CDC also recommends providing resources about safe teen driving for parents of teenagers.[43]

Proper use of adult restraints includes wearing the seat belt at all times and making sure that the lap and shoulder belts are properly positioned across the pelvis and ribcage. The shoulder belt should be placed across the middle of the chest and away from the neck; the lap belt should be secured below the stomach and across the hips.[46] Women who are pregnant should be advised to wear a seat belt with the shoulder strap laying across the chest (between the breasts) and away from the neck. The lap belt should be secured below the abdomen so that it fits snugly across the hips and pelvic bone, as illustrated in **Figure 5-1**. Pregnant women should be further advised to adjust the seat as far back as possible, such that the foot pedals can be comfortably operated and at least 10 inches is maintained between the chest and the steering wheel.[47]

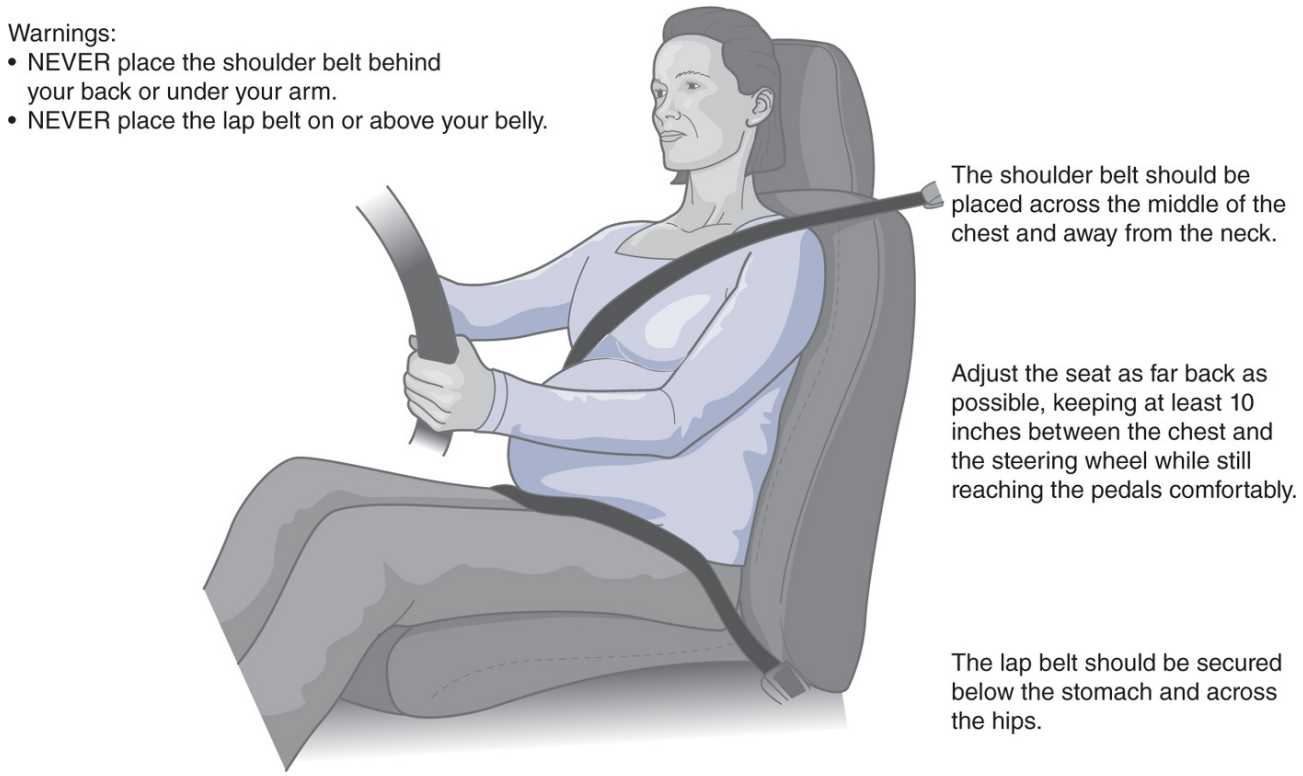

Figure 5-1 Proper placement of seat belt for women during pregnancy.

One third of automobile accident–related deaths in the United States involve drunk driving, and there are no identified harms associated with counseling about driving and drinking.[43] Counseling to reduce the incidence of driving under the influence of alcohol or other drugs is similar to counseling about the use of motor vehicle safety restraints. One approach is to include information about "drinking and driving" in behavioral counseling interventions for individuals who screen positive for alcohol misuse.[24] Counseling should include a discussion about determining a designated driver and establishing a plan for alternative transportation when in the company of an impaired driver.

Distracted driving is a relatively newly identified phenomenon, and interventions to prevent morbidity and mortality related to this practice have not been evaluated by the USPSTF. *Distracted driving* refers to driving while doing other things—most specifically, talking on a cell phone and sending/reading text messages. In 2015, nearly 3500 persons were killed and 391,000 persons were injured in the United States in motor vehicle accidents caused by distracted driving.[48] As is true for counseling about the dangers associated with drinking and driving, counseling about the dangers associated with distracted driving, with strong recommendations to refrain from talking on hand-held cell phones and sending/reading text messages, may result in fewer distracted driving–related automobile accidents.

For women age 65 years and older, falls are the leading cause of injury-related death and the most common cause of nonfatal injuries and trauma-related hospitalization.[49] The USPSTF recommends regular exercise or physical therapy and vitamin D supplementation for falls prevention in women age 65 years and older who are at increased risk for falls.[50] One way to assess a woman's fall risk is to ask her three questions:

1. Have you fallen in the past year?
2. Do you feel unsteady when standing or walking?
3. Do you worry about falling?

A "yes" response to one or more of the questions signals a positive screen.[51]

Recommendations for exercise include participation in weight-bearing exercises, leg-strengthening exercises, and exercises that improve balance (such as Tai Chi) at home or in group exercise classes.[50] The recommended dose of supplemental vitamin D for individuals at increased risk for falls is 800 IU per day.[50] Additional recommendations to reduce falls in women age 65 years and older include the identification of, and warning women about, medications that cause dizziness or drowsiness; reducing tripping hazards in the home, along with the addition of grab bars and improved lighting; and yearly eye examination with update of corrective lenses as needed.[51]

Physical Activity

Adequate physical activity is a factor in the prevention of heart disease, type 2 diabetes, obesity, infertility, some cancers, osteoporosis, osteoarthritis, falls, anxiety and depression, and premature death for both women and men.[52] During the collection of a complete health history, specific questions about activity interests and motivation can facilitate discussion about types of activities in which a person regularly participates. The midwife is then able to compile a comprehensive picture of nutrition status, activity levels, and lifestyle choices, as well as risk factors for certain diseases that may be minimized with physical activity.

Recommendations for counseling about physical activity are primarily based on risk factors. Intensive behavioral counseling interventions that include physical activity and diet are recommended for persons who are overweight or obese and who have additional risk factors for cardiovascular disease.[38]

Multicomponent recommendations for women with a BMI of 30 or higher and women who are overweight and have risk factors for cardiovascular disease include several behavioral management activities, such as goal setting, individual and group counseling and/or exercise sessions, making dietary and physical activity changes, recognizing and addressing barriers to change, and long-range planning to maintain lifestyle changes.[39] Although much of the counseling aimed at improving physical activity can begin with the primary care provider, the most effective interventions are delivered by specially trained professionals such as exercise professionals, physical therapists, or health educators.[39]

For women who are not obese and who do not have risk factors for cardiovascular disease, the USPSTF found a positive but small net benefit from exercise counseling conducted by primary care providers.[40] In the absence of risk factors for cardiovascular disease, the decision to provide exercise counseling is based on the individual woman's healthcare needs. Women who are ready to make behavioral changes are most likely to benefit from such counseling.[40]

To help women increase their physical activity level, it is necessary to know about the resources available in the community and to think creatively about ways to encourage effective

physical activity. While some women may have access to gyms or exercise studios with certified fitness professionals, many other women will prefer to use resources available in their neighborhood. Walking or running in the local neighborhood, along with participating in community, school, or workplace activity groups, may be among the most effective methods of increasing physical activity for most women. It is important that midwives understand the safety parameters of the communities in which they live and work so that they will be prepared to recommend safe spaces for women to exercise. When helping women with special needs (e.g., acute or chronic illnesses), knowledge of group exercise programs designed for individuals with specific health conditions can be invaluable.

For a woman with an established exercise routine, the goal is to support and encourage her participation in a beneficial exercise regimen. For women who participate in little or no physical activity, the challenge is to help them make small, incremental steps toward a more active lifestyle. Physical activity recommendations for women across the lifespan are presented in **Table 5-7**.[52] The CDC has additional information about various forms of physical activity, such as aerobic versus strength training, and ways to measure the intensity of physical activity.[53]

Table 5-7 Physical Activity Recommendations for Women Across the Lifespan

Age	Recommendation
Adolescents (age 17 years and younger)	≥ 60 minutes of moderate or vigorous aerobic activity each day Include muscle strengthening activities in the 60 minutes at least 3 days per week Include bone strengthening activities in the 60 minutes at least 3 days per week
Adults (age 18–64 years)	150 minutes[a] of moderate-intensity aerobic activity each week and muscle-strengthening activities that work all major muscle groups on ≥ 2 days per week OR 75 minutes[a] of vigorous-intensity aerobic activity each week and muscle-strengthening activities on ≥ 2 days per week OR An equivalent mix of moderate- and vigorous-intensity aerobic activity each week and muscle-strengthening activities that work all major muscle groups on ≥ 2 days per week
Older adults (age 65 years and older)[b]	150 minutes[a] of moderate-intensity aerobic activity each week and muscle-strengthening activities that work all major muscle groups on ≥ 2 days per week OR 75 minutes[a] of vigorous-intensity aerobic activity each week and muscle-strengthening activities on ≥ 2 days per week OR An equivalent mix of moderate- and vigorous-intensity aerobic activity each week and muscle-strengthening activities that work all major muscle groups on ≥ 2 days per week
Pregnant and postpartum women	150 minutes[a] of moderate-intensity aerobic activity per week Healthy women who participate in vigorous-intensity aerobic activity prior to pregnancy may continue to do so during and after pregnancy as long as they stay healthy and discuss their exercise activity with their healthcare provider.

[a] May be broken into increments as small as 10 minutes at a time.

[b] Who have no limiting health conditions and are generally fit.

Based on Centers for Disease Control and Prevention. Physical activity basics. 2015. Available at: https://www.cdc.gov/physicalactivity/basics/index.htm. Accessed July 11, 2017.[52]

Documentation in the health record should include findings of the health history, health risk assessment, and BMI. Documentation should also include a description of the counseling and/or referral that was provided and plans for follow-up.

Sexually Transmitted Infections and Risk for Unplanned Pregnancy

Sexually transmitted infections (STIs) are a preventable cause of morbidity and mortality in the United States, with an estimated 20 million new STIs diagnosed each year, almost half of which are diagnosed among individuals age 15–24 years.[54] Recognizing that all sexually active adolescents are at risk for STIs, the USPSTF recommends intensive behavioral counseling for STI prevention for all sexually active adolescents[54] and for all adults at increased risk for STIs. Women at risk for STIs include those with a current STI or an infection within the past year, women who have multiple sexual partners, women who do not consistently use condoms, and women who live in communities with high prevalence rates of any STI.[54]

The most effective counseling interventions are those that are delivered over the course of 2 or more hours, although sessions as brief as 30 minutes can be effective. Effective counseling sessions can be provided in group or individual settings, and delivered over single or multiple sessions. The most effective counseling interventions provide information about STIs and their transmission, assessment of STI transmission risk, and training in essential skills such as condom use, talking about safer sex, goal setting and problem solving.[54] The *Reproductive Tract and Sexually Transmitted Infections* chapter contains a detailed discussion of STIs and STI prevention.

The USPSTF has not made recommendations or addressed the prevention of unplanned pregnancy. However, the most recent data indicate that 45% of pregnancies in the United States are unintended, down from 51% in 2008.[55] To meet the *Healthy People 2020* goal of decreasing the rate of unintended pregnancy to 44%,[56] it is likely that some form of intervention in the primary care setting will be necessary. Prior to initiating a discussion about pregnancy prevention, the midwife asks the woman about her plans regarding pregnancy. A review of contraceptive options is conducted for women who are not planning a pregnancy. A detailed discussion of contraceptive methods is presented in the *Family Planning* chapter. For women who are planning a pregnancy, the midwife completes the implementation of the health promotion plan as described in this chapter with a focus on topics of particular import for pregnant women as reviewed in Appendix 5A. Documentation in the health record should include findings of the sexual health history and a description of the counseling and/or referral that was provided.

Skin Cancer Prevention

Skin cancer is the most common cancer in the United States. Basal and squamous cell carcinomas, which are the two most common forms, are highly curable.[57] By comparison,

melanomas, most of which are caused by ultraviolet (UV) light exposure,[57] result in more than 9000 deaths in the United States each year.[58] Fair-skinned adolescents and young adults through the age of 24 years should be counseled about minimizing their risk for skin cancer by decreasing exposure to UV light.[59] Because the lifetime risk for skin cancer is strongly linked to UV exposure early in life, the USPSTF was unable to determine the net effect of counseling individuals older than 24 years. However, it found little harm associated with such counseling and recommends that decisions to provide counseling about UV exposure be made based on risk factors.[59]

In addition to reviewing the risks for skin cancer associated with UV exposure and avoiding sun exposure between the hours of 10:00 a.m. and 4:00 p.m., use of a broad-spectrum sunscreen with a sun-protection factor (SPF) of 15 or more and use of protective clothing, a wide-brimmed hat, and sunglasses are recommended. All persons should also be counseled to avoid using indoor tanning facilities.[59,60]

Tobacco Use

The top four leading causes of death in women—heart disease, cancer, chronic respiratory disease, and stroke—can all be linked to tobacco use.[12] Although tobacco use among both women and men has declined over the past several decades, smoking remains the leading cause of preventable death in the United States.[61] Surpassing breast cancer in 1987, lung cancer is now the leading cause of cancer death in women in the United States.[61] In addition to lung and several other forms of cancer, the health risks associated with tobacco use include cardiovascular disease; diseases related to the endocrine system, including diabetes; menstrual dysfunction, including early menopause; osteopenia/osteoporosis; and premature death.[61]

Women who smoke during pregnancy are at increased risk for ectopic pregnancy and spontaneous abortion, preterm labor and birth, preterm premature rupture of membranes, placental abruption, placenta previa, intrauterine growth restriction, and perinatal mortality.[62-64] Infants born to women who smoke during pregnancy are at increased risk for neonatal death, sudden infant death syndrome (SIDS), and low birth weight.[62-64] Finally, environmental exposure to cigarette smoke on the part of nonsmokers—a phenomenon characterized as *secondhand* or *passive smoke*—contributes to early death in almost 41,000 nonsmoking adults and 400 infant deaths each year.[65] Some authorities are studying smoke retained in cars, rooms, and clothing, termed *thirdhand smoke*, to ascertain whether risks exist in those situations.

Smoking cessation at any age is associated with reductions in smoking-related disease and early death, and women who stop smoking before or during pregnancy can significantly reduce their risk for adverse pregnancy outcomes.[64] Therefore, primary preventive strategies focus on assisting current smokers to stop and reducing the number of individuals who have ever smoked.

Healthcare providers should ask all patients, including pregnant women, about tobacco use. Individuals who use tobacco are advised to stop and provided with behavioral interventions aimed at cessation of tobacco use.[64] It is also recommended that pharmacotherapy approved by the U.S. Food and Drug Administration (FDA) be provided for all nonpregnant women and

men who use tobacco. There is insufficient evidence to assess the balance of benefits and harms related to pharmacotherapy for smoking cessation in pregnant women.[64]

One of the most effective and efficient behavioral counseling interventions for women who use tobacco is based on the 5 A's construct (ask, advise, assess, assist, arrange), as shown in **Table 5-8**.[66] Convincing evidence indicates that even brief counseling interventions (lasting 3 to 10 minutes), either alone or in combination with pharmacotherapy, can effectively increase the number of smokers who quit and remain abstinent for one year.[64] Pharmacotherapy for smoking cessation includes nicotine replacement therapy (found in gums and lozenges) as well as the medications bupropion (Wellbutrin) and varenicline (Chantix). The effectiveness of and harms associated with these agents during pregnancy is not well documented.[62,63]

Table 5-8 **Modified 5 A's for Smoking Cessation**

Ask every woman about tobacco use.

Advise every woman who smokes to stop smoking and provide information about the risks associated with continued use.

Assess every woman's readiness and/or willingness to stop smoking. This includes identifying barriers and motivating factors to stop smoking.

Assist women to stop smoking. This includes setting goals to cut down/quit, providing support, identifying sources of social support, and dealing with motivational barriers.

Arrange for regular follow-up visits with the midwife and/or refer to additional healthcare providers for more intensive treatment if necessary.

Based on Agency for Healthcare Research and Quality. Five major steps to intervention (the "5 A's). 2017. Available at: https://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/tobacco/5steps.html. Accessed June 11, 2017.[66]

Smoking cessation interventions may be briefly reviewed in midwifery education programs. One survey of CNMs and CMs found that approximately 50% of the respondents were aware of the USPSTF guidelines and 5 A's intervention.[67,68] However, a recent pilot study found that midwife-delivered 5 A's smoking cessation was effective in decreasing the number of cigarettes smoked per day and increasing the number of women who stopped smoking during pregnancy.[69] Although this was a small pilot study, the findings indicate that use of the modified 5 A's smoking cessation program can be incorporated into midwifery practice.[62,68] In addition, it is essential to conduct this kind of counseling in a nonjudgmental way, to individualize counseling interventions during pregnancy, and to include information about health risks for both the woman and her child.[64]

Most women who smoke are fully aware of the health risks associated with smoking and experience feelings of guilt and shame about continuing the unhealthy behavior. These feelings are especially prevalent among women who smoke during pregnancy and among women who relapse after a cessation attempt. Counseling interventions for women are most effective when the relationship between the midwife and the woman is based on mutual trust and respect and when the intervention is woman centered. Rather than attempting to manipulate pregnant women to stop smoking by instilling feelings of guilt and fear about the fetal effects of smoking, a more effective approach is to engage women in an open and respectful dialogue, where the

primary focus of the discussion is on maintaining and promoting the personal health of the woman. Documentation in the health record should include findings of the health history regarding tobacco use, a description of the counseling and/or referral that was provided, and plans for follow-up.

Immunizations

Immunization against several disease states is a primary preventive strategy for women across the lifespan.[70],[71] General immunization recommendations from the CDC for adolescents, women of childbearing age, and women of perimenopausal/menopausal age are summarized in **Table 5-9**.[70] However, it is important to understand that these recommendations are frequently updated so that timing and doses may change. Among the changes in the revised 2018 recommendations will be additional information about vaccines in pregnancy. Readers are advised to consult the CDC website frequently for the current recommendations. A link to the CDC immunization schedules can be found in the Resources section at the end of this chapter. An app is available for clinicians who need this information at their fingertips. Midwives who administer immunizations are also encouraged to consult the relevant Advisory Committee on Immunization Practices (ACIP) statements, available on the CDC's website, for recommendation updates, special recommendations for women with immunocompromising conditions, and guidelines for vaccinations for healthcare workers, and travelers. Adverse events following vaccination should be reported to the Vaccine Adverse Event Reporting System (800-822-7967). Links to vaccine-related resources, including vaccine schedule apps, are provided in the Resources section at the end of this chapter.

Table 5-9 **Immunization Schedule for Women Across the Lifespan[a]**

Vaccine	Adolescents	Women Age 19–41 Years	Pregnant Women	Women Age ≥ 41 Years	Dose/Series, Timing and Other Considerations
Hib (*Haemophilus influenzae* type b conjugate vaccine)	Recommended only for adolescents with anatomic or functional asplenia (including sickle cell disease) or HIV infection who have not been previously immunized	Recommended only for women with certain immunocompromising conditions	Recommended only for women with certain immunocompromising conditions	1 or 3 doses depending on the indication for vaccination	See CDC guidelines for additional information.
HepA (hepatitis A)[b]	Recommended only for adolescents who live in areas with vaccination programs targeting older children, adolescents at increased risk for hepatitis A, and for adolescents for whom immunity is desired	Only women who have not been previously immunized and who are at increased risk for infection or desire protection[b]		Only women who have not been previously immunized and who are at increased risk for infection or desire protection[b]	Single antigen hepatitis A vaccine (HepA; Havrix) given as a two-dose series with 6–12 months between doses (Havrix) or a two-dose series with 6–18 months between doses (VAQTA). Alternatively, a three-dose series of combined hepatitis A and hepatitis B vaccine (HepA–HepB) may be used; the second dose is given 1 month following the first dose and the third dose is given 6 months following the first dose.
HepB (hepatitis B)	All adolescents not previously immunized	Only women who have not been previously immunized and who are at increased risk for infection or desire protection (see CDC guidelines)		Only women who have not been previously immunized and who are at increased risk for infection or desire protection (see CDC guidelines)	Complete vaccination requires a three-dose series: second dose given 4 weeks following the first dose; third dose given 8 weeks after the second dose (and at least 16 weeks after the first dose). Two-dose series (separated by 4 months) of adult formulation *Recombivax HB* may be used in girls 11–15 years.
Herpes zoster vaccine	NA	NA	NA	All women ≥ 60 years	One-time dose; no need for revaccination. **Contraindicated for persons with certain medical conditions** (see CDC guidelines).

HPV (human papillomavirus) vaccines:[c] Gardasil (4vHPV) Gardasil 9 (9vHPV)	All adolescents 11 or 12 years Women 13–26 years if not previously immunized	All women < 26 years if not previously immunized Pregnancy testing not required prior to administration	HPV vaccines are not recommended in pregnancy, though there is no evidence that the vaccine poses harm. If pregnancy is discovered after the first dose is given, completion of the series should be postponed until the woman is no longer pregnant; no additional intervention is necessary	All women < 26 years if not previously immunized	Complete vaccination requires a two-dose series: second dose given 6–12 months following the first dose. Adolescents initiating the vaccine at ≥ 15 years should receive three doses; administer the second dose 1–2 months after the first dose and the third dose 6 months after the first dose.
Influenza IIV (inactivated influenza)	All girls ≥ 9 years LAIV is not recommended for individuals < 18 years	All women	All adults, including pregnant women, can receive IIV	All women	Inactivated influenza vaccine comes in two formulations: inactivated influenza and recombinant influenza. Both are safe to use for all ages and during pregnancy. A single dose is administered each year, just prior to (or following) the start of the flu season. Contraindicated for persons with severe allergy to vaccine components, history of Guillain-Barré syndrome within 6 weeks of receipt of vaccine, or severe illness with fever (delay until illness is resolved). LAIV is a nasal spray and is contraindicated during pregnancy and during some flu seasons. See CDC guidelines.
Influenza: RIV (recombinant influenza vaccine)	All girls ≥ 9 years LAIV is not recommended for individuals < 18 years	All women	Contraindicated in pregnant women and in girls with asthma or underlying conditions that predispose them to influenza complications	All women	Recombinant influenza vaccine.
IPV (inactivated poliovirus)	Recommended only for girls < 18 years if not previously immunized	NA	NA	NA	Complete vaccination requires a three-dose series: second dose given 4 weeks following the first dose; third dose given 4 weeks after the second dose.

MMR (measles, mumps, and rubella)	Recommended only for girls not previously immunized	Regardless of birth year, women of childbearing age should have laboratory-confirmed rubella immunity Women who are not considered immune should receive the vaccine Vaccinate nonpregnant women during menses when nonpregnant status is certain	Contraindicated in pregnancy and for individuals who are immunocompromised Pregnant women without evidence of laboratory-confirmed immunity should be vaccinated immediately postpartum or following pregnancy termination	Women who are not considered immune	Complete vaccination requires administration of two doses separated by at least 4 weeks. Second dose is necessary only for women who are college students, women who work in a healthcare facility, and women who plan to travel internationally. Women who received inactivated measles vaccine or vaccine of unknown type from 1963 to 1967 should be revaccinated with two doses of MMR.
Meningococcal vaccines	Menactra or Menveo 11–12 years, with booster at age 16 years Catch-up vaccine given at 13–18 years if not previously immunized	MenACWY, MPSV4 Women who are first-year college students through age 21 years who live in residence halls and who were not previously vaccinated on or after their 16th birthday, HIV-positive, traveling to a country where the disease is prevalent or living in an area of outbreak, and military recruits	May be used if at risk for serogroup A, C, W, or Y	MenACWY, MPSV4 If not previously vaccinated or had disease	If first dose is received at $\geq$ 16 years, no booster is required. One-time single dose. Revaccination 5 years following first dose is necessary only for women who remain at increased risk for infection. There are several different meningococcal vaccines based on serotypes. Indications for each vaccine are different. See the CDC guidelines for additional information and scheduling recommendations for women with immunocompromising conditions and other risk factors for infection.
PCV (pneumococcal conjugate) or PPSV (pneumococcal polysaccharide)	NA	NA	Women $<$ 65 years only if they smoke, live in long-term care facilities, or have chronic lung disease, chronic cardiovascular disease, diabetes mellitus, chronic liver disease, alcoholism, cochlear implants, cerebrospinal fluid leaks, immunocompromising conditions, or functional anatomic asplenia (including sickle cell disease)	Women vaccinated before 65 years should be revaccinated at 65 years	Recommended vaccine types and interval spacing vary based on the indication for early vaccination. See the CDC guidelines for additional information and scheduling recommendations for women with immunocompromising and other serious medical conditions.

Tdap (tetanus diphtheria, and acellular pertussis)	All girls 11–12 years;18 years if not previously immunized	Single dose recommended for all pregnant women at 27–36 weeks' gestation during each pregnancy (regardless of number of years since last Td or Tdap vaccination)	Recommended for all adults. Substitute Tdap for Td once, then every 10 years	Recommended for all adults. Substitute Tdap for Td once, then every 10 years	Administer one dose with each pregnancy. A three-dose series is recommended for all adults with unknown or incomplete vaccination history: first two doses administered at least 4 weeks apart; third dose administered 6–12 months after the second dose.
VAR (varicella)	Only girls without evidence of immunity[d]	Contraindicated during pregnancy Pregnant women should be evaluated for laboratory-confirmed varicella immunity. Those without evidence of immunity should begin the two-dose vaccination series *immediately postpartum* or following pregnancy termination	Women without evidence of immunity only	Women without evidence of immunity only	Complete vaccination requires administration of two doses separated by at least 4 weeks for girls ≥ 13 years. For girls 7–12 years, the doses should be separated by 3 months. Evidence of immunity includes documentation of previous vaccination with two doses at least 4 weeks apart, history of herpes zoster diagnosed by a healthcare provider, history of varicella diagnosed by a healthcare provider, or laboratory-confirmation of immunity. Laboratory confirmation should be obtained for women who report having had a mild or atypical case of varicella.

Abbreviations: CDC, Centers for Disease Control and Prevention; HAV, hepatitis A virus; HIV, human immunodeficiency virus; LAIV, live attenuated influenza vaccine; NA, not applicable; Td, tetanus and diphtheria toxoids.

[a] See CDC guidelines for current immunization schedule.
[b] Women for whom hepatitis A vaccination is recommended include those who (1) use illicit drugs, (2) work with HAV-infected primates or HAV in laboratory settings, (3) have chronic liver disease, (4) receive clotting factor concentrates, (5) travel or work in countries with high or intermediate rates of hepatitis A, or (6) anticipate close contact with children from countries with high or intermediate rates of hepatitis A during the first 60 days after arrival in the United States (childcare providers or adoptive parents).
[c] HPV vaccination recommendations apply to male and female adolescents.
[d] Evidence of immunity = documented previous immunization or laboratory-confirmed evidence of immunity.

Based on Centers for Disease Control and Prevention. Recommended immunization schedules for adults aged 19 years or older—United States, 2017. 2017. Available at: https://www.cdc.gov/vaccines/schedules/hcp/adult.html. Accessed June 23, 2017.[70]

Health Maintenance: Secondary Prevention

In addition to primary preventive services to promote health and prevent the onset of disease, midwives provide secondary preventive services aimed at maintaining health through early detection and treatment of several disease states across the lifespan.

Routine Screening Across the Lifespan

After completing the health history and physical examination, additional screening information is obtained with the collection of laboratory tests. Recommendations for these tests are based on the existence of identified individual risk factors such as gender and age. Screening tests for asymptomatic women for which there is sufficient evidence to recommend are summarized in **Table 5-10**.[72] Screening test recommendations for pregnant women are presented in the *Prenatal Care* chapter.[72] These recommendations are reviewed regularly and are revised based on the findings of new evidence; readers are therefore encouraged to become familiar with and regularly access updated recommendations at the USPSTF website. Links to resources for preventive health services, including an electronic preventive services selector tool (ePSS), are found in the Resources section at the end of this chapter.

Table 5-10 **Recommended Routine Screening Tests**[a]

Disorder	Adolescents Age < 18 Years	Women Age ≥ 18 Years	Test Used	Screening Recommendation
Abnormal glucose and type 2 diabetes mellitus	Not indicated unless risk evident on history or physical examination	Women age 40–70 years who are overweight or obese	HbA1c *or* fasting plasma glucose *or* oral glucose tolerance test	Screening frequency is unknown, but every 3 years is suggested. Refer women with abnormal blood glucose for intensive counseling interventions to promote a healthy diet and increased physical activity.
Alcohol misuse	Insufficient evidence	Age ≥ 18 years	AUDIT, AUDIT-C, or single question screen	No evidence for screening frequency.
Breast cancer	NA	≥ 50 years, and screening at age 40 years made on an individual basis	Screening mammogram	Every 2 years until age 75 years. Insufficient evidence to recommend for or against screening for women age ≥ 75 years. Women with a family history of breast or ovarian cancer should be referred for genetic counseling and possible BRCA testing (see counseling recommendations described earlier in this chapter).
Cervical cancer	USPSTF recommends against screening women < 21 years unless at high risk	≥ 21 years	Cytology (Pap test)	Every 3 years until age 65 years. HPV testing combined with cytology (co-testing) every 5 years is acceptable for women age ≥ 30–64 years who prefer less frequent screening. Screening not recommended for women ≥ 65 years if adequately screened and not at high risk, or with history of hysterectomy without history of precancer or cervical cancer.

Colorectal cancer	NA	50 years Earlier if history of first-degree relative with early-onset colorectal disease	Fecal occult blood or DNA testing, sigmoidoscopy, CT colonography, or colonoscopy	Recommendations for appropriate screening intervals are controversial and should be made based on clinical findings. The decision to screen women age 76–85 years is made on an individual basis. Colonoscopy has greatest sensitivity and specificity for colorectal cancer screening. USPSTF found no studies that demonstrated greater effectiveness of any screening tool.
Chlamydia	All sexually active adolescents Recommended frequency depends on new or persistent risk factors since the last negative screen	All sexually active women ≤ 24 years Older women who are at increased risk for infection	Nucleic acid amplification tests	Nucleic acid amplification tests can be used with urine and vaginal swabs if a pelvic examination is not performed.
Depression	All adolescents age 12–18 years	18 years	PHQ-A or BDI-PC for adolescents Any reliable screening tool for adults	USPSTF also recommends ensuring that systems are in place to ensure accurate diagnosis, treatment, and follow-up. See the *Mental Health Conditions* chapter for a review of reliable screening tools, screening frequencies, and management of a positive screen.
Gonorrhea	All sexually active adolescents	All sexually active women ≤ 24 years and older women who are at increased risk for infection	Nucleic acid amplification tests	Recommended frequency depends on new or persistent risk factors since the last negative screen. Nucleic acid amplification tests can be used with urine and vaginal swabs if a pelvic examination is not performed.
Hepatitis B	Screen all adolescents and young adults at increased risk for infection, including those who have been vaccinated	All women at risk for infection	HBsAG	Anti-HBs and anti-HBc tests are done as part of a panel to distinguish between immunity and infection.
Hepatitis C	Screen all women at risk for infection	Offer screening to all women born between 1945 and 1965 Rescreen women at continued risk periodically	Anti-HCV antibody test; confirm with polymerase chain reaction testing	The most significant risk factor is past or current illicit IV drug use. Receiving a blood transfusion before 1992, long-term hemodialysis, incarceration, intranasal drug use, being born to a woman infected with hepatitis C, and getting a tattoo from an unregulated vendor are also risk factors. Women born between 1945 and 1965 have higher rates of hepatitis C than other women.

Human immunodeficiency virus (HIV)	All adolescents age ≥ 15 years	Unknown; suggested one-time screen for all women age 15–65 years, with repeat screens based on risk factors	Repeatedly reactive immunoassay and confirmation with Western blot	See the *Reproductive Tract and Sexually Transmitted Infections* chapter for review of risk factors and management of a positive screen.
Hypertension	Not indicated for routine screening	Yearly for women ≥ 40 years and for younger women with risk factors for hypertension Every 3–5 years for women age 18–39 years without a history of or risk factors for high blood pressure	Blood pressure measured with sphygmomanometer	USPSTF has found insufficient evidence to recommend for or against routine blood pressure measurements in children. Blood pressures should be taken with the woman seated at least 5 minutes after entering the examination room. Ensure use of a proper-size cuff and placement of the woman's arm at the level of the heart. Use the mean of two measurements taken at a single visit; confirm diagnosis with measurements take outside of the clinical setting.
Intimate-partner violence (IPV)	All adolescents 14–17 years	All women of childbearing age	Any reliable screening tool	Screening tools with high sensitivity and specificity for IPV identification include: Hurt, Insult, Threaten, Scream (HITS); Ongoing Abuse Screen/Ongoing Violence Assessment Tool (OAS/OVAT); Slapped, Threatened and Throw (STaT); Humiliation, Afraid, Rape, Kick (HARK); Modified Childhood Trauma Questionnaire—Short Form (CTQ-SF); and Woman Abuse Screen Tool (WAST). All women are at risk for IPV, and women age 14–46 years are at greatest risk. There is insufficient evidence to recommend for or against screening of younger girls and older women. Therefore, USPSTF makes no recommendation for or against screening girls < 14 years or women > age 46 years.
Latent tuberculosis infection	Yearly if at risk	Unknown; one-time screen may be sufficient with yearly screening for those at continued risk	Mantoux tuberculin skin tests or interferon-gamma release assays	Women at increased risk for latent tuberculosis infection include those who were born or lived in countries with high prevalence rates and those who live in high-risk settings (such as homeless shelters and correctional facilities). Consult local health departments to determine populations at risk in their community.

Lipid disorders	Insufficient evidence to recommend for or against screening for individuals < 40 years	40–75 years Frequency is every 5 years via expert opinion	Nonfasting or fasting total cholesterol, LDL-C, and HDL-C	These recommendations for cholesterol testing are part of a recommendation for the use of statins in adults with increased risk for CVD. Determining CVD risk requires assessment of cholesterol levels as recommended here.
Lung cancer	NA	55 years, then annually for women with a history of smoking	Low-dose computed tomography	Screen all women age 55–80 years who have a 30-pack-year smoking history and currently smoke or quit smoking in the past 15 years. Screening may be discontinued 15 years after the woman quits smoking.
Obesity	All	All	BMI	Those who are obese or overweight should be referred for intensive behavioral interventions to improve weight status. See the counseling interventions in this chapter.
Osteoporosis	NA	65 years	DXA scan of the hip and lumbar spine	Earlier screening is recommended for women with fracture risk ≥ that of white women age 65 years without risk factors. Rescreening should not occur sooner than 2 years following initial screening. Risk factors include Caucasian race, smoking, daily alcohol use, BMI < 21, and parental history of fracture.
Syphilis	Only those at increased risk for infection	Adults at increased risk for infection	VDRL or RPR—confirmed with FTA-ABS or TP-PA	Women at risk include those with HIV, commercial sex workers, certain racial and ethnic groups, and those who live in high-prevalence areas.
Tobacco use	All	All	Health history	Screen all adolescents. See the screening and counseling recommendations in this chapter.

Abbreviations: Anti-HBc, hepatitis B core total antibodies; anti-HBs, hepatitis B surface antibody; AUDIT, alcohol use disorders identification test; AUDIT-C, alcohol use disorders identification test—consumption; BDI-PC, Beck Depression Inventory for Primary Care; BMI, body mass index; CT, computed tomography; CVD, cardiovascular disease; DXA, dual-energy X-ray absorptiometry; FTA-ABS, fluorescent treponemal antibody-absorption test; HbA1c, hemoglobin A1C; HBsAG, hepatitis B surface antigen; HCV, hepatitis C virus; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; NA, not applicable; PHQ-A, Patient Health Questionnaire for Adolescents; RPR, rapid plasma reagin; TP-PA, treponemal pallidum particle agglutination assay; USPSTF, U.S. Preventive Services Task Force; VDRL, Venereal Disease Research Laboratory test.

[a] Unless otherwise indicated, these are the screening recommendations for healthy adolescents and women who are not at increased risk for infection or disease. Adolescents and adults with risk factors may require more frequent screening or screening with the use of additional tests and/or procedures.

Based on U.S. Preventive Services Task Force. Published recommendations. 2017. Available at: https://www.uspreventiveservicestaskforce.org/BrowseRec/Index/browse-recommendations. Accessed July 4, 2017.[72]

In addition to the recommendations made by the USPSTF, other groups such as the American College of Obstetricians and Gynecologists and the American Cancer Society have made

recommendations for screening that are often slightly different than the USPSTF recommendations. Healthcare facilities may adopt guidelines from different sources when establishing their institutional policies and procedures. Individual communities may also have "community standards" based on these recommendations. Therefore, it is essential that midwives remain aware of the recommendations of other groups and recommendations made based on community standards.

Reproductive Life Planning and Preconception Care

Reproductive life planning refers to a woman designing a set of personal reproductive goals and a plan for how to achieve those goals. Preconception care is a set of interventions that aim to identify and modify biomedical, behavioral, and social risks to the woman's health and her subsequent pregnancy outcomes through prevention and management. Preconception care is addressed separately from the rest of health promotion across the lifespan for two reasons: (1) Some health promotion interventions can directly influence perinatal outcomes, and (2) preconception care includes both primary and secondary health promotion activities.

Reproductive Life Planning

The CDC and other public health organizations have recommended reproductive life planning and preconception care,[73,74] though the evidence supporting preconception care as a package of services is sparse. Although strong evidence supports the value of specific healthcare services such as folic acid supplementation,[75] only a small number of women currently receive preconception care; in addition, health outcomes following preconception care as a package of services have not yet been well validated in research studies. The lack of positive evidence for preconception care may be at least partly related to women's lack of access to the multidisciplinary support and continuum of services that are the most effective interventions.

One of the critiques of preconception care is that this set of primary and secondary prevention strategies has value for women across the lifespan, not just during the time prior to childbearing. One of the dangers of viewing health care for women in such a way that prioritizes healthcare delivery based on plans for a future pregnancy rather than the general wellbeing of women is the presumption that every woman will attempt or want a pregnancy in the future. Moreover, given that approximately 45% of all pregnancies are not planned,[76] some experts in this field argue that a broader focus on optimal health behaviors for all women of reproductive age will be of greater benefit. The ACNM takes the position that "the health of a woman is a primary goal, independent of her reproductive life plan."[77]

Putting aside the controversy over these issues, it is clear that some adverse perinatal outcomes can be prevented via preconception identification of risks and use of risk-reduction strategies. Chronic diseases that are associated with adverse pregnancy outcomes are common among women of childbearing age.[76] In addition, reproductive life planning for women who do not want to become pregnant could help these women identify acceptable methods of contraception and improve spacing of births.

This section reviews the components of health promotion that relate specifically to pregnancy outcomes. The content included in a preconception care visit is presented in Appendix 5A. A woman-centered approach to initiating a discussion about reproductive goals is presented in **Table 5-11**.[78]

Table 5-11	Screening Strategies That Facilitate Reproductive Goals Counseling
Strategy	**Question(s) Included In Strategy**

One Key Question	Would you like to become pregnant in the next year?
Pregnancy **A**ttitudes, **T**iming, and **H**ow important is prevention (PATH)	1. Do you think you might like to have (more) children at some point? 2. If you are considering becoming a parent in the future, when do you think that might be? 3. How important is it to you to prevent pregnancy (until then)?

Based on Callegari LS, Aiken AR, Dehlendorf C, Cason P, Borrero S. Addressing potential pitfalls of reproductive life planning with patient-centered counseling. *Am J Obstet Gynecol.* 2017;216(2):129-134.[78]

The initial *one key question* will help direct the conversation. If a woman indicates that she is not planning a pregnancy in the near future, the next step is to determine whether she is at risk for becoming pregnant (i.e., engaging in heterosexual vaginal sex and possibly fertile), and if so, her desire to avoid pregnancy. A thorough review of contraceptive options and contraceptive counseling can be found in the *Family Planning* chapter. If a woman wants to become pregnant in the near future, the midwife continues with preconception care evaluation as presented in Appendix 5A.

Conclusion

Health promotion is an essential component of care provided by midwives, which is accomplished through the delivery of primary and secondary preventive services. Primary preventive services, which include counseling/education and vaccination, are provided to healthy individuals as a means to prevent the onset of disease. Secondary preventive services, which include evidence-based screening and early intervention, are provided to limit morbidity and mortality related to disease. As primary care providers who often see clients at regular intervals across the lifespan, midwives are well positioned to provide the preventive services described in this chapter and to offer individuals the tools necessary to become active participants in their own health maintenance and to achieve optimal levels of wellness.

Introduction

Preconception care is founded on the basic principle that healthy women tend to have healthy offspring. The period of time before a woman is pregnant can be critical to promote and maintain her health during pregnancy. Targeted care during the preconception period can lead to identification and modification of risks that can influence not only a woman's health, but the health of her future child and society as a whole.[1] **Table 5A-1** defines terms commonly encountered in this area.[2-6]

Table 5A-1 Definitions of Terms

Term	Definition
Preconception care	Multiple definitions exist, but in all cases the goal is to provide care to reproductive-age women that promotes a woman's health and identifies and modifies her risks to promote a healthy pregnancy if or when it ensues.
Preconception period	The time before or between pregnancies. Some publications focusing on care of the pregnant woman have also called this span the *prepregnancy period* or *interconception period.*
One Key Question	A screening strategy using one question to promote efficient identification of an individual's intentions regarding pregnancy.
Reproductive life plan (RLP)	An individual's plan that reflects future intentions for reproduction. It should not be assumed that an RLP means that a pregnancy is planned; the RLP should be accepted at face value without judgment.

Based on American Academy of Pediatrics, American College of Obstetricians and Gynecologists. Prepregnancy care. In: *Guidelines for Perinatal Care.* 8th ed. Preconception care: improving the health of women and families. *J Midwifery Womens Health*. 2016;61(3):356-364.[6]

The clarion call to action for preconception care was first sounded more than 30 years ago.[7] Since then, various controversies have arisen, predominantly focused on the strategies surrounding preconception care. For example, some groups have advocated an *Every Woman, Every Visit* approach, in which nonpregnant women are screened at every clinical encounter. Unfortunately, this strategy can be interpreted as a requirement to provide intensive health counseling and rigorous education about pregnancy for all women, raising concerns that such an approach could be viewed as pronatalism because it ignores the fact that some women may never desire to be pregnant.[8] Other healthcare professionals have expressed concerns that time spent with women not intending to become pregnant within the near future may be too narrowly focused and has a vocabulary that may disengage women.[9] None of these concerns questions the utility of preconception care, and a new approach to the concept addresses these issues.

Preconception Care

Today's approach to preconception care is to ask any individual who is of reproductive age *One Key Question*. This question is most commonly phrased as follows: *Would you like to become pregnant in the next year*? The key question is a critical part of a *reproductive life plan (RLP)*.[4] The answer should be documented in the woman's health record and the question regularly revisited because the woman may change the answer as their circumstances change. The key question is neutrally phrased and enables the professional to target health education, and thus, time during the healthcare visit, to the needs of the individual. **Figure 5A-1** provides an algorithm for use in providing care to reproductive-age women.

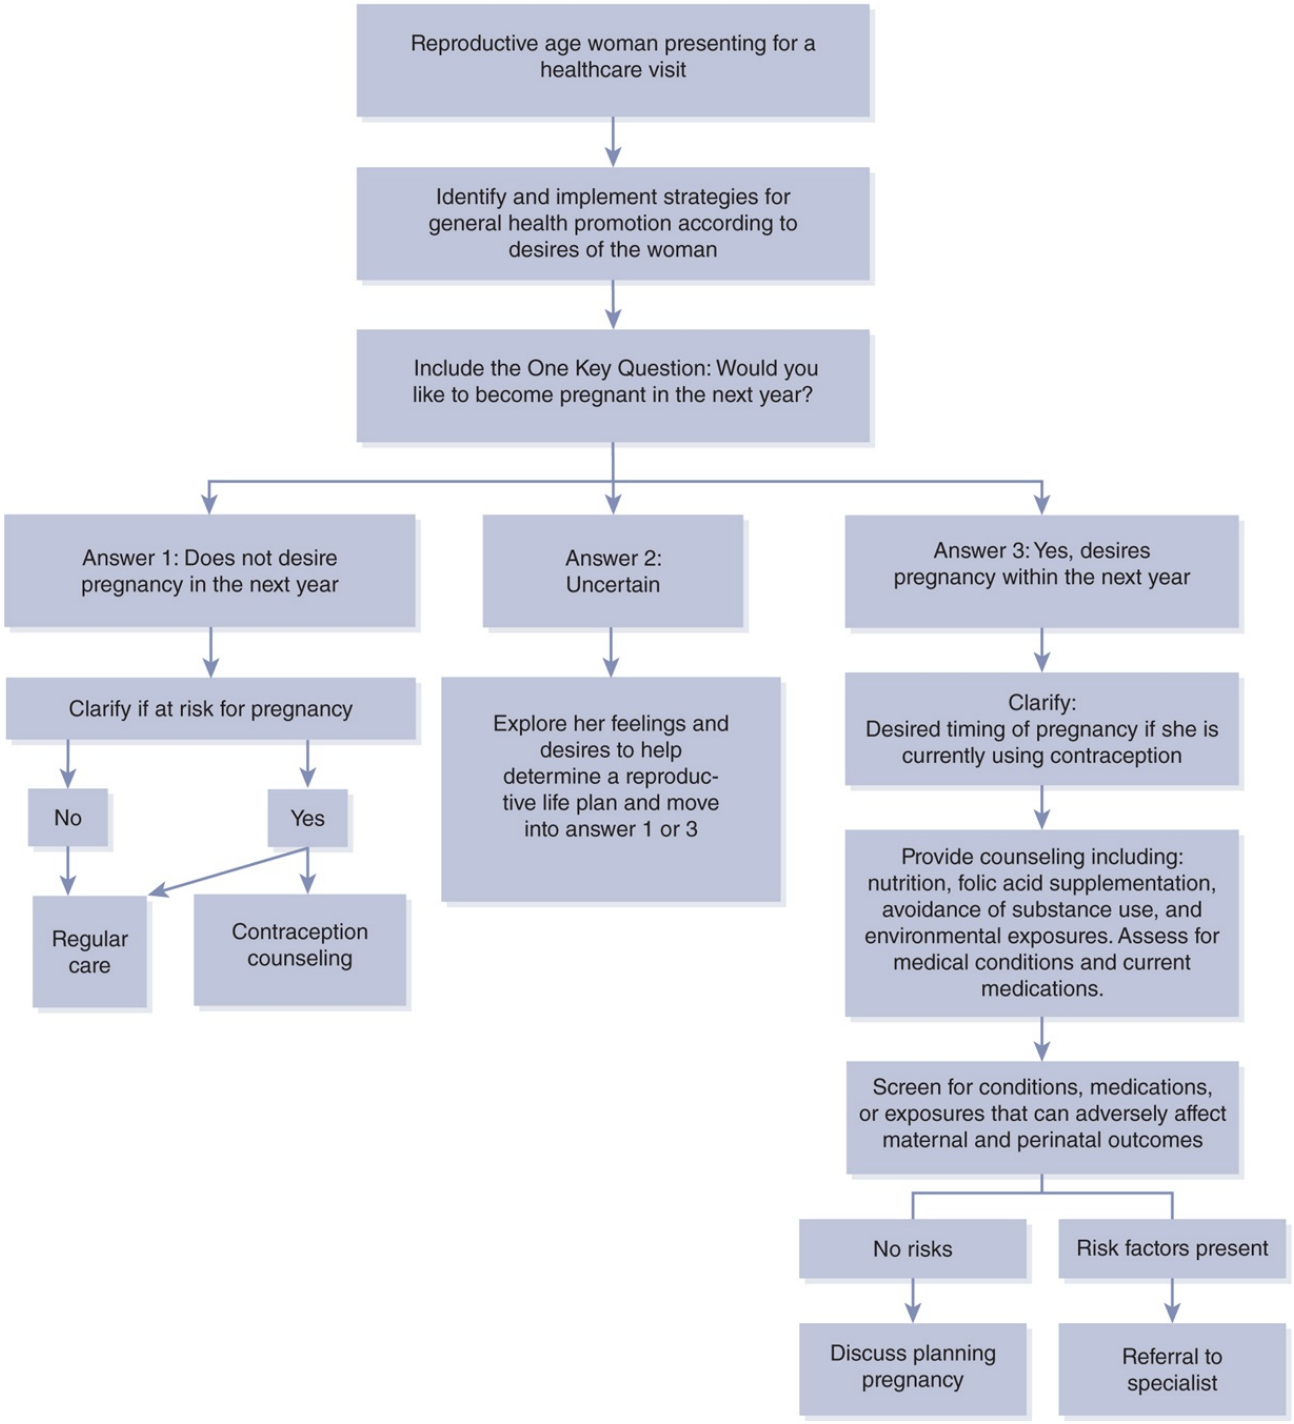

Figure 5A-1 Algorithm illustrating the use of One Key Question.

A midwife is most likely to meet women who provide one of three answers to the key question. For all of these women, health promotion—as discussed in the *Health Promotion Across the Lifespan* chapter—is an essential component of care.

For women who answer "1" (does not plan to get pregnant in the next year) who are at risk for pregnancy, time with the midwife can be best focused on identifying a reliable contraceptive method that she desires and can use consistently and correctly, as described in

the *Family Planning* chapter.

Individuals who answer the key question with "2" (uncertain about whether or not they are planning a pregnancy in the next year) can be helped to reflect and develop a reproductive life plan. Although ultimately a woman will determine that she does or does not plan a pregnancy in the coming year, many women will choose contraception while they ponder how to design their reproductive life plan.

Women who respond that they wish to become pregnant in the next year (answer 3 to the key question) are the women for whom this appendix is written. These women are planning a pregnancy within the next 6 months or 1 year. More information about use of the key question and details about preconception care can be obtained from the National Preconception Health and Health Care Initiative (PCHHC), a public/private partnership of more than 70 organizations. Its website, Before, Between & Beyond, is an extensive and credible source of information about individuals in the preconception period and is included in the Resources table at the end of this appendix.[10]

General Health Promotion and Preconception Care

All women can profit from health promotion, as discussed in the *Health Promotion Across the Lifespan* chapter. However, women who are planning pregnancy within the near future merit a review of some topics that can impact the course of pregnancy.

Substance Use

Counseling that is particularly important during a preconception visit includes recommendations regarding substance use. Women who use alcohol during pregnancy run the risk that their child will develop a fetal alcohol spectrum disorder, including fetal alcohol syndrome, the most severe form. Smoking or other tobacco use remains the leading preventable cause of premature death for women in the United States, despite the declining rate of use over the last few years. Tobacco is fetotoxic and is associated with an increased incidence of low birth weight in newborns who were exposed in utero. Particular attention also should be paid to the increasing number of women dealing with opioid use: Opioid use is harmful to the woman and also associated with neonatal abstinence syndrome. The preconception period represents an opportunity for women to seek help in changing their patterns of use and misuse of these substances, particularly since it usually takes time and sometimes several attempts to quit successfully.[2]

Several myths exist regarding oral health in pregnancy. Some women may have heard that loss of teeth is inherently associated with pregnancy and, therefore, may not seek dental care while pregnant. Other women may avoid such care due to fear of risk of X rays. In any case, research has demonstrated an increased risk of preterm birth when women have significant periodontal disease during pregnancy.[11] This increase in the incidence of preterm birth in conjunction with periodontal disease is likely linked to the inflammatory process. Ideally, dental work necessary to correct periodontal disease or dental caries should be completed

prior to pregnancy.

Immunizations

Evidence exists that several vaccines are effective interventions to promote healthy pregnancies when administered prior to pregnancy in women without immunity.[12] All women of reproductive age should have their immunization status for tetanus–diphtheria–acellular pertussis toxoid (Tdap); measles, mumps, and rubella (MMR); hepatitis B; and varicella reviewed annually. If immunity is lacking, these immunizations should be offered. Current recommendations are to give one dose of Tdap to every pregnant woman during every pregnancy (27–36 weeks) regardless of the duration of time since the last Tdap vaccination. This is true for all pregnant women, even those vaccinated preconceptionally. Women at risk for acquiring hepatitis B or who have not received the vaccine should be offered the immunization series prior to pregnancy.

Rubella is a known teratogen, causing congenital rubella syndrome when nonimmune women are infected during the first 16 weeks of pregnancy. Women who receive the rubella immunization should be counseled to avoid pregnancy for 1 month, based on a theoretical risk of passing rubella to a developing embryo. However, there are no reports of teratogenicity secondary to receiving rubella vaccine in early pregnancy; thus, pregnancy termination is not recommended for women who are inadvertently vaccinated for rubella within 4 weeks of becoming pregnant or when they are pregnant.[13]

Nutrition: Dietary Counseling and Folic Acid Supplementation

All women should be counseled to avoid vitamins or multivitamin preparations that exceed the current recommended daily allowances because of the potential adverse effects associated with higher doses. For example, vitamin A is associated with fetal malformations if very high doses of supplements are consumed in the first trimester. In addition, some nutritional supplements can adversely interact with absorption of foods or medications, so it is important to review and educate women about all medication use when taking multivitamins.

Most women in the United States do not consume the recommended amounts of folate from diet alone. All professional organizations recommend that women planning a pregnancy or capable of becoming pregnant take a supplement that has 400 to 800 micrograms of folic acid per day to reduce the risk of having a fetus with a neural tube defect.[15] Most over-the-counter multivitamins contain 400 micrograms (0.4 milligrams) of folic acid, and generic preparations are appropriate.

Vitamin D deficiency is widespread, yet data is still emerging with regard to the value of vitamin D supplementation. At present, regular screening of pregnant women for vitamin D deficiency and supplementation of vitamin D during pregnancy (beyond the amount included in a multivitamin) are not recommended. However, clinicians may consider screening women at increased risk of vitamin D deficiency, such as those who live in cold climates and along northern latitudes, those who wear sunscreen regularly, and those who belong to a racial/ethnic group with dark skin.[16] When a deficiency is identified, ingestion of 1000-4000 IU/day is

considered to be reasonable and safe by most experts.[16]

Decreasing Environmental Risks

The most common environmental toxins in the United States and their known health effects are listed in **Table 5A-2**. The adverse effects of environmental toxins is the subject of a great deal of research and new knowledge is rapidly emerging.[17-24] No woman can totally avoid exposure to toxins. Naturally occurring substances, such as lead and cadmium, are not toxic at low levels; however, human activity has resulted in concentrated levels and increased exposure to these substances. Even though lead has been banned from fuel mixes in the United States for several decades, lead from automobile exhaust continues to contaminate soil and water, especially in the land near busy highways. Lead-based paint continues to present exposure risks in older homes and playgrounds that were constructed before these paints were banned.

Table 5A-2 Environmental Toxins with General and Reproductive Effects

	General Effects					Reproductive Effects									
Agent/Source of Exposure	**Cancer**	**Increased BMI**	**Neurologic Impairment**	**Thyroid Dysfunction**	**Genomic Methylation Alternations**	**Spontaneous Abortion**	**Preterm Birth**	**Stillbirth**	**Decreased Birth Weight**	**Impaired Fetal Growth**	**Impaired Neurologic Development[a]**	**Congenital Malformations**	**Reduced Sperm Quality**	**Post-Term Birth**	**Breastfeeding Effects When Known**
Lead: Battery manufacture, smelting, soldering, firearm manufacture, lead-based paints, lead pipes, ceramics, jewelry, folk medicines, hair dyes, contaminated soil			X		X						X				Most common heavy metal found in breast milk
Mercury: Coal-fired plants, contaminated fish			X								X				Found in breast milk
Arsenic: Wood preservative, mining, manufacturing	X														Found in breast milk
Cadmium: Mining, industrial pollution	X														Least common heavy metal found in breast milk
Pesticides, organophosphates, organochlorines, organohalogens: Agriculture, landscaping, pest control	X		X							X	X		X	X	Levels decreasing in breast milk samples during 2000s
Solvents (benzene, toluene, xylene, styrene, bromopropanes, perchloroethylene): Plastics, synthetic fibers, dyes, detergents, lubricants, printing, insulation, leather tanning, cleaning products, fiberglass, carpet backing						X			X			X			
Phthalates: Medical devices, building materials, cosmetics, pharmaceuticals, food processing, toys							X				X				
Polychlorinated biphenyls: Industrial insulators and lubricants	X	X							X		X		X		May be present in breast milk

Perchlorate: Rocket fuel, fireworks, bleach, fertilizers	X										May be present in breast milk
Perfluorochemicals, Perfluorooctane sulfonate (PFOS): Nonstick cookware, water-resistant packaging, food containers, manufacturing		X				X			X		Present in breast milk samples of women from many countries; effect unknown
Polybrominated diphenyl ethers: Flame retardant, furniture, textiles, carpeting, electronics				X	X	X		X			Levels increasing in breast milk samples during 2000s
Bisphenol A: Plastics, resins, packaging			X					X			
Formaldehyde: Wood adhesives, abrasive agents, clinical laboratory preservative, embalming			X			X					
Antineoplastic drugs: Chemotherapy			X			X					
Anesthetic gases: Human and veterinary surgery			X						X		
Ethylene oxide: Sterilizing gas for heat-sensitive medical items and surgical instruments			X	X							
Ozone, carbon monoxide, nitrogen dioxide, sulfur dioxide, lead, particulate matter: Air pollution						X		X	X		
Cigarette smoke			X	X		X				X	

[a] Impaired neurologic development includes abnormal brain development, mental disability, lowered IQ, aggressive behavior, attention-deficit disorder, hyperactivity, and executive function deficits.

Environmental chemicals in pregnant women in the United States: NHANES 2003–20004. *Environ Health Perspect.* 2011;119(6):878-885.[24]

The most prevalent environmental toxins are manufactured chemicals, including pesticides, polychlorinated biphenyls, and perfluorochemicals. Most of these chemicals degrade slowly and are absorbed by humans through ingestion of contaminated food and water or inhalation of particles. Environmental toxins have broad deleterious effects on reproductive health, including decreased sperm quality, congenital anomalies, increased spontaneous miscarriage, stillbirth, low birth weight, and preterm labor. Many environmental toxins also cross the placenta and have been found in cord blood and fetal tissue as well as breast milk.

An important first step in decreasing exposure to environmental toxins is risk identification through the collection of a thorough history of occupational, recreational, residential, or dietary exposures. Counseling should include sources of environmental toxins and approaches used to limit exposure. To conduct this kind of counseling, midwives need a working knowledge of local and regional environmental pollutants, including soil contaminated by past and present industry and agricultural pesticides. Midwives can also provide guidance to reduce exposure to toxins for all women, including recommendations to rinse fruits and vegetables to remove pesticide residue and to avoid consuming contaminated foods.

Special Considerations

A complete history may reveal reproductive problems including extremes of age, genetic conditions of the woman or family, and chronic illnesses and treatments. In these situations, preconception care can be invaluable.

Risk for Genetic Disorders

Knowledge about genetic inheritance, screening, and counseling has exploded during this century. Collection of a three-generation history is needed to identify genetic conditions. If a specific risk factor is identified or if the future parents have concerns, referral to a genetic specialist is required.[2] Population genetics suggest that some screening can be focused by ethnic or racial backgrounds. For example, Ashkenazi Jews have a higher risk of Tay–Sachs disease than other groups. Sickle cell disease is more common among African Americans, while cystic fibrosis has a higher incidence among Northern Europeans.

When a woman has been identified as a carrier for a condition, her reproductive partner should also be offered screening. In the event that a referral for genetic counseling is necessary, midwives must remain sensitive to the costs and insurance coverage of genetic counseling services and provide women with affordable options. A detailed discussion of this entire subject is found in the *Genetics* chapter.

Reproductive History

Previous adverse pregnancy outcomes suggest the need for additional attention in the preconception period. For example, women who have had a previous pregnancy complicated by complications such as preterm birth or fetal growth restriction are at risk for similar outcomes in a subsequent pregnancy. If the etiology of a previous adverse perinatal outcome is known, further assessment and therapies may be instituted preconceptionally to mitigate recurrence risks.[25,26] Health education about birth spacing, nutrition, and healthy habits often are useful in improving outcomes.

Effect of Maternal Age on Reproductive Outcomes

Declines in fertility and adverse reproductive outcomes are more likely as women become older—specifically, after age 35 years.[2] In addition, as women age, their risks for diabetes, hypertension, and other chronic diseases increase. These chronic conditions independently increase the risk for poor perinatal outcomes. Thus, it is often difficult to distinguish the risks that are secondary to age from those that are secondary to a combination of age and a chronic condition.

The effects of age on reproductive outcomes form a continuum. Although 35 years is often used as a cut-off for identifying women at increased risk, most of these risks increase incrementally over time. Based on a woman's reproductive life plan discussion with women approaching this age may consider a variety of options related to fertility and pregnancy, including egg banking and other aspects of reproductive artificial technology—topics beyond the scope of this appendix.[27]

Medical Conditions

Women who have medical conditions that can adversely affect pregnancy (e.g., diabetes, hypertension, epilepsy, autoimmune disorders) should be referred for care by a specialist prior to attempting pregnancy. **Table 5A-3** lists selected chronic health conditions that can adversely affect the course of pregnancy, though it is not all-inclusive.[25,28-34] Several of these conditions have risks associated with the disease; others require treatments that may be teratogenic or fetotoxic.

Table 5A-3 Preconception Care Interventions for Chronic Medical Conditions

Medical Condition	Evidence-Based Interventions
Asthma	Inhaled corticosteroid therapy for asthma control may be associated with low birth weight, gastroschisis, and increased risk of preeclampsia. Women with asthma should be evaluated, the condition optimally stabilized, and medications carefully chosen before a woman becomes pregnant.
Autoimmune conditions (e.g., rheumatoid arthritis, systemic lupus erythematosus)	Some medications commonly used to treat autoimmune conditions, such as methotrexate (Trexall), are teratogens. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) in the first trimester does not appear to be associated with fetal anomalies; however, NSAIDs are contraindicated later in pregnancy due to their effect in keeping the ductus ateriosus open.
Cardiovascular disease	Perinatal outcomes are closely associated with the severity of the heart disease (e.g., minimal risks exist associated with mitral valve prolapse; pulmonary hypertension is potentially life threatening).
	Warfarin (Coumadin) use in pregnancy is associated with embryopathy.
Diabetes	Good glycemic control (i.e., HbA1c < 6.0%) at the time of conception lowers the risk of miscarriage and congenital anomalies that are associated with hyperglycemia.
Hypertension	Use of ACE inhibitors and ARBs is associated with increased risks of fetal malformation, oligohydramnios, fetal growth restriction, and fetal death.
	Women with long-standing hypertension may have silent ventricular hypertrophy, retinopathy, and renal disease, requiring evaluation by a specialist prior to pregnancy.
IPV	IPV has been associated with preterm birth, low birth weight, postpartum depression, and even maternal mortality. Interventions before pregnancy can focus on helping the woman find a safe environment.
Mental health conditions	Although debate continues regarding the potential teratogenic effects of some psychotropic agents, there is a general consensus that the benefits associated with treatment generally outweigh the risks because mental health disorders in pregnancy are associated with poor obstetric outcomes, higher risk of postpartum psychiatric illnesses, increased rates of substance abuse, lower participation in prenatal care, and adverse infant outcomes.
Obesity	Considered the most common of the chronic diseases, obesity during pregnancy increases maternal risks of hypertensive disorders and gestational diabetes as well as preterm birth, birth defects, and perinatal death.
	Education and counseling during the preconception period can assist a woman in losing weight in a healthy manner before attempting pregnancy. Weight-loss drugs should be avoided, as they may be associated with increased risk of congenital anomalies when used in pregnancy.
Renal disease	Because women who have severe renal disease are likely to experience a worsening of the condition during pregnancy, including severe associated conditions such as hypertension, these women should be carefully counseled by a specialist and their medications evaluated prior to

	becoming pregnant.
Seizure disorders	Many anticonvulsants are known teratogens but based on the woman's seizure pattern may be prescribed because their risks can be outweighed by their benefits.
	Preconception counseling for women affected by seizure disorders has been shown to increase the likelihood of successful withdrawal to monotherapy and to positively impact birth outcomes.
Thyroid disorders	Medications for hyperthyroidism may be associated with congenital anomalies. The general recommendation is to avoid pregnancy for 6 months after receiving radioactive treatment.
	Overt hypothyroidism during a woman's first trimester of pregnancy is associated with dwarfism and intellectual impairment. Other pregnancy complications associated with hypothyroidism include miscarriage, preterm birth, preeclampsia, placental abnormalities, and low birth weight.

Medications

Medications used by the woman, including herbal preparations, botanicals, and over-the-counter agents, should be evaluated for potential teratogenic effects, and the continuing need for the medication should be assessed. Women should not be automatically counseled to discontinue medications because they are considering pregnancy, as this may negatively affect their medical or mental health. Ideally, a plan should be in place for use of any specific medication in the preconception period and during the early stages of organogenesis. When a woman reports taking a medication that has identified risks during pregnancy, the midwife should discuss the implications with the woman and recommend safer alternative medications as available.

Preparing for Pregnancy

The decision to seek pregnancy is unique to each woman. A preconception visit enables her to optimize her health. Health is more than the mere absence of disease, and exploration about a women's level of stress, socioeconomic stability, family dynamics, support networks, and other social determinants of health can also be explored during this time.[35] Short interpregnancy spacing, as defined as 6 months or less, has been found to be an independent risk factor for adverse perinatal outcomes, and that information may influence a woman's timing of pregnancy.[36]

The preconception period is also an ideal time for women and/or couples to consider their access to and availability of health care. An essential question to consider at a preconception visit is whether the woman wishes to see a midwife, obstetrician-gynecologist, family practice physician, or maternal–fetal medicine specialist when pregnant. Place of birth and provider options may be controlled by the woman's insurance carrier and subject to certain limitations. If couples investigate these options early, they may be able to make the arrangements for the birth provider and the environment they need and prefer.

While most midwives provide little care for men, male partners of a woman planning a pregnancy should also be encouraged to develop a reproductive life plan. Should they have a history of personal or family health conditions, they should also obtain an evaluation of their health and potentially genetic counseling.

Although many providers recommend using a barrier method for a set period of time before discontinuing contraception completely, this recommendation is based on the convenience of establishing a normal menstrual period that can be used to determine an estimated date for birth rather than evidence that pregnancy outcomes are improved if conception is delayed. After using a hormonal method of contraception, the first menses may be anovulatory or ovulation may occur quickly. When ovulation does occur quickly, a woman might conceive prior to having a menstrual period, which makes gestational dating by last menstrual period less reliable. Women should be reassured that conceiving prior to the first menstrual period is not associated with an increased risk of spontaneous abortion or congenital anomalies.

As a general guideline, a woman who is seeking pregnancy, engaging in regular intercourse, and not using any contraceptive method will usually become pregnant within a year. If pregnancy does not ensue after 12 months, an infertility evaluation for the woman and her partner can be initiated. Alternatively, some women age 35 years or older may wish to seek infertility care after only 6 months of failing to become pregnant because fertility wanes with increasing age.

Conclusion

Preconception is an important topic for healthcare providers and women alike. A healthy woman is more likely to have a healthy newborn. Health care during the preconception period verifies that a woman is healthy; provides an opportunity to treat a woman who has a disorder; and promotes health education, counseling, and habits that are congruent with a healthy pregnancy, and birth. Preconception care does not need to be pronatalistic or cost unnecessary time in the clinical area. By using the One Key Question, care can be focused appropriately on the care of the woman during the clinical encounter.

CHAPTER

6

Common Conditions in Primary Care

Introduction

Historically, midwives have been healers in their communities. In addition to attending births, a midwife often was the herbalist, first responder, and health counselor. Thus, midwives were among the original primary care providers. Today, midwives continue to be primary care providers and are often the first point of contact for women in the healthcare system.[1] Midwives have the training and expertise to conduct screenings, counsel and monitor women in making healthy behavior changes, diagnose and manage minor illnesses and some chronic diseases, and determine to whom and how to refer to other experts in the field as more complicated situations arise. This chapter is an introduction to health problems commonly experienced by women. More in-depth information can be obtained in primary care texts that address these conditions.

Primary Care

No universally accepted definition of “primary care” exists. Variations exist among insurers, providers, professional organizations, and consumers. Perhaps the most widely accepted definition is the one issued in 1996 by the Institute of Medicine, which characterized primary care as:

> *The provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community.*[2]

For some individuals, the “large majority” has been defined as provision of 80% of the care needed by a person annually. However, this definition of primary care fails to highlight the importance of health maintenance, age-appropriate screening, and health education—all activities are that are discussed in depth in the *Health Promotion Across the Lifespan* chapter.

It is increasingly appreciated that social determinants of health can dramatically affect the health of a woman and her family. Organizations such as the Centers for Disease Control and Prevention (CDC), National Institutes of Health (NIH), and Health Resources and Services Administration (HRSA) have called for integration of population health into primary care with the goal of creating a more unified approach to care.[3] This chapter reviews care of women who are not pregnant, but who have disorders or conditions that can be characterized as in the realm of primary care rather than gynecologic care.

Hematologic Conditions

Anemia

Anemia is defined as a decrease in red blood cell mass or decrease in hemoglobin. Most often, anemia remains a “silent” condition unless it is acute or severe. Signs and symptoms of anemia are listed in **Table 6-1**.[4] Anemia can be caused by decreased red blood cell production, increased red blood cell destruction, or blood loss, and is diagnosed in nonpregnant women when the hemoglobin level is less than 12.0 g/dL.[5] This cut-off was established by the World Health Organization for use in international nutrition studies and does not apply to all populations. For example, African American women have, on average, hemoglobin levels approximately 1 g/dL lower than those in whites, regardless of socioeconomic level.[5] Women who smoke (because of competition for oxygen-binding sites on red blood cells) and women living at high altitudes (because of lower oxygen concentration in the atmosphere) have higher hemoglobin and hematocrit levels: Their bodies adapt to maintain adequate oxygenation and their hemoglobin levels increase as the altitude or number of cigarettes smoked per day increases.[5] Thus, the hemoglobin level that indicates anemia may vary based on an individual’s personal health profile. The U.S. Preventive Services Task Force does not address whether screening for anemia should be a routine part of health care for nonpregnant women.[6]

Table 6-1 **Signs and Symptoms of Severe Anemia**

Signs	Symptoms
Pallor	Fatigue, drowsiness
Jaundice	Weakness
Orthostatic hypotension	Dizziness
Peripheral edema	Headaches
Pale mucous membranes and nail beds	Malaise
Smooth, sore tongue	Pica
Splenomegaly	Poor appetite, changes in food preferences
Tachypnea, dyspnea on exertion	Changes in sleep habits
Tachycardia or flow murmur	Changes in mood

Differential Diagnosis of Anemia

Anemia can be acquired as occurs in iron deficiency, or hemorrhagic anemia, or it can be inherited as occurs in persons with hemoglobinopathies, such as thalassemia or sickle cell disease. Anemia can be subclassified different ways. Subclassification by etiology refers to anemia secondary to decreased red blood cell production or increased red blood cell destruction. Alternatively, anemia can be subclassified as normocytic, microcytic, or macrocytic depending on the amount and type of hemoglobin present in red blood cells as reflected in the mean corpuscular volume (MCV). The clinical evaluation and diagnosis of anemia is based on MCV, which is how this chapter reviews this condition.

Anemia is commonly categorized by the size of the red blood cells. *Microcytic anemias* include iron deficiency, the thalassemias, and anemia of inflammation. *Macrocytic anemias* include folate and vitamin B12 deficiency, as well as anemia associated with liver disease, increased reticulocyte production, and some medication effects. *Normocytic anemias* commonly reflect acute blood loss or conditions such as sickle cell disease, hemoglobin C disease, or glucose-6-phosphate dehydrogenase (G6PD) deficiency. Aplastic anemia, while normocytic, is characterized by pancytopenia, meaning a reduction in the number of red blood cells (RBCs), white blood cells (WBCs), and platelets. **Table 6-2** lists the laboratory values associated with some common causes of anemia.

Table 6-2 Laboratory Values Associated with Common Anemias

Laboratory Test	Iron Deficiency	Vitamin B_{12} Deficiency	Folate Deficiency	Thalassemia	Chronic Disease
Red blood cells (RBCs)	Low	Low	Low	Normal	Low
Hemoglobin (Hgb)	Low	Low	Low	Low	Low
Mean corpuscular volume (MCV)	Low	High	High	Low	Normal-low
Mean corpuscular hemoglobin (MCH)	Low	High	High	Low	Low
Reticulocytes	Low	Low	Low	High	Low
Ferritin	Low	High	High	Normal–high	Normal–high
Iron	Low	High	High	Normal–decreased	Low
Total iron-binding capacity (TIBC)	High	Normal	Normal	Variable	Low
Other		Low vitamin B_{12}	Low folate	Teardrop red cells	
		Elevated methylmalonate	Normal methylmalonate	Target cells	
		Elevated homocysteine	Elevated homocysteine	Abnormal hemoglobin electrophoresis	

A complete blood count (CBC) provides the first level of assessment and helps differentiate many of the underlying causes of anemia. If a woman has menstrual periods, the history and review of systems should include obtaining a history of how heavy her menstrual flow is, even though the accuracy of women's estimation of their flow has been demonstrated to vary. A prior diagnosis of anemia merits a description of the circumstances and helps guide the differential diagnosis. For women with a hemoglobin value of less than 12.0 g/dL, a laboratory panel including serum folate and ferritin measurements should be ordered, and a hemoglobin electrophoresis performed. The ferritin level is the most sensitive and specific predictor of iron stores and, therefore, true iron deficiency.

Iron-Deficiency Anemia

The most common anemia in the United States is due to iron deficiency, which usually is mild and easily reversible. The Recommended Daily Intake (RDI) of iron for reproductive-age women is 15 mg for girls from 14 to 18 years and 18 mg for women from 19 to 50 years.[7] Following menopause, the RDI drops to 8 mg. The diets of most women in the United States include approximately 13–14 mg of iron daily. Normal daily iron loss through excretion, sweat, and cellular shedding amounts to 1 mg; menses causes an additional monthly loss. Pregnancy-related demands increase the daily iron need among reproductive-age women. RDI for pregnant women set at 27 mg per day.

Occult blood loss, excessive menstrual loss, and inadequate nutritional intake which is more likely among vegetarians, are the most common causes of iron deficiency in adults. If nutritional deficiency is ruled out and in the absence of an identifiable source of bleeding such as heavy menses, inquiry about use of aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) as well as assessment for gastrointestinal bleeding is warranted. Nutritional deficiencies causing significant iron depletion include restrictive vegetarian diets as well as pica; therefore, a careful diet history is part of the work-up.

A ferritin level less than 100–150 ng/mL confirms the diagnosis of iron-deficiency anemia and renders serum iron and total iron-binding capacity measurements unnecessary. Based on the severity of the anemia and its cause, consultation or referral may be indicated; when the hemoglobin indicates severe anemia (< 9.0 g/dL), consultation is appropriate, even when the anemia is clearly caused by iron deficiency.

First-line treatment is to increase dietary intake of iron-rich foods, along with consumption of vitamin C–enriched products to enhance absorption of the heme iron. Nutritional counseling should stress the importance of including iron-rich foods in the diet—such as green leafy vegetables, collard greens, egg yolks, raisins, prunes, liver, oysters, and some fortified cereals—as well as the elimination of picas (e.g., eating ice or laundry starches). A detailed discussion of dietary sources of iron can be found in the *Nutrition* chapter.

Iron supplementation, either through the diet or with oral medications, should be recommended for a nonpregnant adult woman when the hemoglobin is less than 12.0 g/dL.[7] When uncomplicated iron deficiency is the cause of the anemia, oral medications are used empirically, including ferrous sulfate, ferrous fumarate, and ferrous gluconate. Each of these preparations is readily available and marketed under several brand names. The equivalent of 325 mg of ferrous sulfate taken three times a day is standard dosing. Generally taking iron preparations with meals will decrease absorption of this nutrient, but will also improve gastrointestinal side effects such as nausea and reflux. Certain drugs, such as antacids, decrease the absorption of iron supplements and should not be taken at the same time. After the hemoglobin level has returned to normal, continued supplementation for 3 months should adequately replenish iron stores in the body.

While no clear standard for follow-up exists, the CBC and reticulocyte count are generally repeated 1–3 months following treatment initiation, depending on the severity of the original deficiency and the age of the woman. Response to iron supplementation is often rapid in cases of uncomplicated iron-deficiency anemia, as evidenced by rebounding hemoglobin and

hematocrit levels and elevated reticulocyte counts. Premenopausal women who are unresponsive to iron therapy and all postmenopausal women with iron-deficiency anemia should be referred for a consultation with a gastrointestinal (GI) specialist. Women may also require referral to a hematologist for further evaluation and possible treatment with intravenous iron therapy if they are unable to tolerate or absorb oral iron therapy. In extreme cases, women may need to be referred urgently to the emergency room for immediate evaluation or blood transfusion if their anemia is severe or symptomatic.

Hemoglobinopathies: Thalassemias

Normal adult hemoglobin is composed of four polypeptide subunits: two alpha-globin chains and two beta-globin chains. A hemoglobinopathy occurs when one or two of the subunits are replaced by a variant type of globin chain. Alpha- or beta-thalassemia occurs when deficient amounts of alpha or beta globin chains are made. Common hemoglobinopathies and thalassemias are listed in **Table 6-3**.

Table 6-3 Disorders of Abnormal Hemoglobin

Name	Description	Clinical Significance
Hemoglobinopathies		
Sickle cell disease	Hb SS	Severe illness with sickle cell crisis
Sickle cell trait	Hb SA	Mild anemia; increased risk for urinary tract infections; sickle cell crisis may occur at high altitudes, if dehydrated, or during extreme physical activity
Sickle cell hemoglobin C disease	Hb SC	Mild to moderate anemia and sickle cell crisis occur but less frequently than in persons with Hb SS; increased risk for infection; risk for retinopathy and blindness in adulthood
Hemoglobin C disease	Hb CC	Usually asymptomatic, may have symptoms associated with splenomegaly. No therapy needed; normal life expectancy.
Hemoglobin C trait	HB CA	Usually asymptomatic
Thalassemias: Alpha-Thalassemias		
Alpha-thalassemia silent carrier	1 of 4 alpha genes deleted	Asymptomatic and difficult to detect
Alpha-thalassemia trait	2 of 4 alpha genes deleted; heterozygous form (i.e., aa/– –) or homozygous form (i.e., a–/a–)	Mild microcytic anemia; individual is asymptomatic
Hemoglobin H disease	3 of 4 alpha genes deleted (i.e., a–/– –), or 2 of 4 alpha genes deleted and the third mutated to the constant spring (cs) form (i.e., – –/aacs)	Enlarged spleen; bone abnormalities; severe illness
Hemoglobin	4 of 4 alpha genes deleted (i.e., – –/– –)	Incompatible with life; causes hydrops fetalis

Bart's hydrops fetalis		
Thalassemias: Beta-Thalassemias		
Beta-thalassemia (Cooley's anemia)	Beta-thalassemia major, homozygous Beta0/Beta0 or heterozygous Beta0/Beta+[a], leading to absence of beta-chain formation	Severe anemia; jaundice; splenomegaly; requires frequent blood transfusions; often experience iron overload. Classic facial features.
Thalassemia intermedia	Beta+/Beta+, resulting in decreased beta-chain formation	Significant anemia but does not need blood transfusions
Thalassemia minor	Normal beta-chain/Beta+ or Beta0	Mild microcytic anemia; individual is asymptomatic

Abbreviations: Beta0, absence of beta-globin formation; Beta+, reduced beta-globin formation.

[a] Depending on the authority, Beta0/Beta+ has been classified as either beta-thalassemia major or intermedia. It is generally less severe than the Beta0/Beta0 presentation because some beta-chain production is possible with Beta+ mutations.

Most thalassemias are autosomal recessive inherited disorders of the globin chains that form normal adult hemoglobin (hemoglobin A). Worldwide, approximately 1.67% of the population is heterozygous for either alpha-thalassemia (α-thalassemia) or beta-thalassemia (β-thalassemia), and approximately 0.044% of the global population is affected by homozygous or multiple heterozygous mutations.[8] However, due to increased immigration from parts of the world where the thalassemias are more prevalent (Southeast Asia, the Mediterranean, Africa, Middle East, and the Indian subcontinent), the prevalence of these conditions has increased by 7.5% in the United States over the last 50 years.[9]

Alpha-thalassemia is most common among individuals of Chinese and Southeast Asian descent. Two genes on chromosome 16 control for alpha-globin chain production. A single deletion will create an asymptomatic carrier state; two deletions will cause a smaller MCV without anemia; and the three-deletion state leads to increased hemoglobin H with effects including splenomegaly and severe hemolytic anemia. The absence of all four alpha chains and the resultant increase in hemoglobin B produces non-immune fetal hydrops, which results in fetal demise.[10]

Beta-thalassemia is most common among women of Mediterranean origin and, to a lesser degree, among Chinese, Asian, and African women. Estimates of its frequency range from 3% to 10%.[11] More than 200 different point mutations can be involved in the beta-globin changes associated with thalassemia, leading to a wide spectrum of disease. Asymptomatic individuals with a mutation affecting a single beta-globin gene may remain in a silent carrier state or may present with only mild anemia (beta-thalassemia minor). For these women, the diagnosis in most likely made based on routine screening or incidental findings. Women with more severe disease—that is, beta-thalassemia intermediate and beta-thalassemia major—have mutations affecting multiple genes. The two conditions are differentiated by the age at diagnosis and degree of anemia, and both require lifelong therapy.[10,11]

The diagnosis of thalassemia is often made in childhood in persons in whom more genes are affected. However, milder presentations may not be identified until later in life, and the

diagnosis is often made for the first time in pregnancy when screening for hemoglobinopathies is commonly performed. Identification of thalassemia in pregnancy is important because a woman with thalassemia, sickle trait, or sickle disease could give birth to a child with a severe hemoglobinopathy if the biological father also is a carrier for abnormal hemoglobin.

Several laboratory findings may suggest the presence of a thalassemia. Among persons with alpha-thalassemias, decreased hemoglobin alpha production causes abnormal proportions of hemoglobins A, A2, and F. The beta-thalassemias are associated with elevated levels of hemoglobin F and hemoglobin A2 (greater than 3.5%). In both cases, the trait will appear as a microcytic anemia in which the MCV is markedly low relative to the hemoglobin level, usually less than 75 femtoliters (fL). The Metzer index is a calculation derived by dividing the MCV by the number of RBCs. When the Metzer index is less than 13, a thalassemia is strongly suspected. Values more than 13 suggest iron-deficiency anemia. Even with values less than 13, a complete anemia panel is justified to rule out a combination of iron deficiency and hemoglobinopathy.

When the diagnosis of thalassemia is established, folic acid supplementation may be employed but iron therapy is inappropriate. The anemia associated with the thalassemias is due to a combination of low hemoglobin production and mild hemolysis, since the abnormal RBCs are more vulnerable to destruction and have a shorter lifespan. Consequently, women with thalassemia may not be iron deficient. Simple iron supplementation will not correct the anemia and can be dangerous if it contributes to iron overload.[10]

Hemoglobinopathies: Sickle Cell Disease

Sickle cell disease (homozygous SS disease) is an autosomal recessive inherited disorder in which hemoglobin S is produced instead of hemoglobin A. Sickle cell trait (Hb AS) is found most commonly among African Americans compared to individuals of other racial and/or ethnic backgrounds. The incidence of sickle cell trait in the United States is estimated to be 73.1 per 1000 black births, 6.9 cases per 1000 Hispanic births, 3.0 per 1000 white births, and 2.2 per 1000 Asian/Native Hawaiian/other Pacific Islander births.[12] Sickle cell trait is rarely associated with hematuria, bacteriuria, and splenic infarct. Although the trait itself is often asymptomatic and does not commonly cause severe health complications, identification of those persons carrying the sickle trait is important to enable appropriate genetic counseling and testing prior to pregnancy. The primary complication for the nonpregnant woman is an increase in the development of urinary tract infections. Interestingly, sickle cell trait may lessen the accuracy of hemoglobin A1C testing, making screening for diabetes in individuals with sickle trait more difficult.

The estimated incidence of sickle cell disease is 1 in 375 births for African Americans and 1 in 16,300 Hispanic births.[13] In sickle cell disease, the Hb S changes shape (polymerizes) when deoxygenated, which causes the RBCs to form a permanent crescent moon or “sickle” shape, such that the RBCs are less able to bend their shape as they traverse through smaller vessels. These sickle-shape RBCs are also more adhesive and clump together to block the microvasculature. Sickle cell crises involve acute episodes of severe pain from ischemia and infarction of tissue and organs downstream from the area of vascular blockage. The disease

has a multi-organ effect and is associated with a shortened lifespan as a consequence of renal damage, cardiac damage, infection, acute chest syndrome, and increased risk for infection. Early death is common. Among a sample of individuals with sickle cell disease living in California and Georgia, the average age of death was 43 years. Approximately 1 out of 6 deaths occurred among individuals younger than 25 years.[14]

Hemoglobin S may also be present in heterozygous form as Hb SC disease or sickle thalassemia (Hb S-B thalassemia), conditions that are associated with somewhat milder forms of sickle crisis. When hemoglobinopathies exist, genetic counseling for couples planning a child is recommended.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked genetic disease found most frequently among individuals of Mediterranean descent and African Americans. Because it is an X-linked condition, G6PD deficiency is rarely symptomatic among women. Even among individuals who have the condition, the clinical presentation ranges from being asymptomatic to presenting with severe acute or chronic hemolytic anemia. Hemolysis occurs when the individual has an infection or receives oxidative drugs. Among the contraindicated medications for women with this disorder are sulfa drugs and sulfa derivatives, nitrofurantoin (Macrobid), nonsteroidal anti-inflammatory drugs (NSAIDs), toluidine blue, and methylene blue. Consumption of fava beans and some other legumes should be avoided as well, because these foods can produce hemolysis among individuals with the Mediterranean variant. Prompt diagnosis and treatment of infection will minimize the risk of hemolysis. Surgery can also precipitate an episode of hemolysis. Therefore, the midwife should either notify the woman's surgical team prior to any surgical procedure or counsel the woman to do so.

Von Willebrand's Disease

Von Willebrand's disease is an autosomal dominant mutation that causes defects in a protein necessary for platelet adhesion and affects clotting factor VII.[15] This condition is related to development of heavy menses approximately 20% of the time, particularly among adolescents.[15] Von Willebrand's disease or another bleeding disorder should be suspected if the woman reports heavy menstrual bleeding in association with prolonged bleeding after surgery or a family history of bleeding problems.[16] The initial assessment includes obtaining a platelet count, ferritin level, and bleeding time and coagulation studies. When platelets are normal, the ferritin level is low, and the bleeding time is prolonged, von Willebrand's disease is a strong possibility. Although the midwife may continue to provide general care, referral of the woman to a hematologist for evaluation is warranted. Women with this condition should avoid aspirin or other agents with anticoagulant properties.

Cardiovascular Conditions

Assessment of a woman's cardiovascular health begins with a history and review of systems that assess for hypertension, cardiac events, and vascular changes in the woman and her immediate family. Assessment of heart sounds and of the pulses during the physical examination is essential, as is an accurate measurement of blood pressure.

Cardiovascular disease is the leading cause of death among women and ranks within the top five causes of death for women of reproductive age.[17] Various forms of cardiovascular disease, including stroke, account for almost 30% of deaths among women. Risk factors for cardiovascular disease include hypertension, dyslipidemia, diabetes, obesity, physical inactivity, and smoking. Simple aging is noted as a risk because 20% of women age 65 years or older have some form of heart disease.

Hypertension

Hypertension—an arterial disease characterized by persistent high blood pressure—is the most frequent diagnosis associated with primary care visits in the United States.[18] Hypertension is a major risk factor for a number of conditions such as coronary artery disease, stroke, heart failure, and renal failure. It is more common among African Americans and among the elderly. More than 30% of all adults in the United States have high blood pressure and the risk increases with age.[19,20] Hypertension is categorized as primary or secondary. Primary hypertension, which is the cause of the majority of hypertension, is thought to be secondary to factors such as genetics, age, and obesity. Secondary hypertension is less common and occurs as the result of another disorder such as a renal or heart condition. A third variation of hypertension is white coat hypertension, which refers to the observation that a person's blood pressure is higher in the presence of a healthcare provider. The prevalence of white coat hypertension ranges from 13% to 35% and is therefore a condition that must be in the differential diagnosis.[20] A fourth variation called masked hypertension refers to individuals who have normal blood pressure during an office visit but hypertension at home. Masked hypertension may occur in 1 in 7 persons. Definitions for blood pressure are listed in **Table 6-4**.20 An estimated 80% of women diagnosed with high blood pressure take medication, although only slightly more than half of those have well-controlled blood pressure.[21] Lack of awareness of a diagnosis of high blood pressure and failure to be treated effectively have been associated with lack of access to care and lack of health insurance.[22]

Table 6-4 **Classification of Blood Pressure for Adults**

Blood Pressure Classification	Systolic (mm Hg)		Diastolic (mm Hg)	Corresponding Values
Normal	< 120	and	< 80	Office reading of 120/80 equals: Home: 120/80 Nighttime ABPM: 100/65
Elevated	120–129	or	< 80	Not defined
Stage 1 hypertension	130–139	or	80–89	Office reading of 130/80 equals: Home: 130/80 Nighttime ABPM: 110/65
Stage 2 hypertension	≥ 140	or	≥ 90	Office reading of 140/90 equals: Home: 140/90 Nighttime ABPM: 140/85 Office reading of 160/100 equals: Home: 140/95 Nighttime ABPM: 140/90

Abbreviation: ABPM, ambulatory blood pressure monitoring.

Based on Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension.* 2017. doi:10.1016/j.jacc.2017.11.006. [Epub ahead of print].[20]

Diagnosis of Hypertension

Several professional organizations in the United States have published guidelines for care of persons with hypertension, which has led to some confusion. The most widely accepted guidelines for the diagnosis and treatment of hypertension were originally established by the Joint National Committee (JNC).[23,24] In 2014, the Seventh Joint National Committee (JNC 7) guidelines were vigorously reviewed by the panel members of the Eighth Joint National Committee (JNC 8), however, the JNC 8 panel was discontinued by the National Heart Lung and Blood Institute. The panel members published their recommendations which focus on pharmacologic management of persons with hypertension.[23] In order to resolve confusion, in 2017, the American Heart Association in conjunction with multiple other professional organizations updated the JNC 7 and published new guidelines for detection, evaluation and management of high blood pressure in adults that are presented in **Table 6-4**.[20]

The initial steps in screening and diagnosis of hypertension are: (1) accurate assessment of blood pressure; (2) identification of signs that suggest primary versus secondary hypertension; (3) screening for other cardiovascular risk factors; and (4) assessment for possible white coat hypertension or masked hypertension.

Accurate Measurement of Blood Pressure. Many clinicians take action based on blood pressure results that are inaccurate because the technique of assessment is incorrect. Blood pressures should always be taken with the cuff at the level of the heart while using a properly

sized cuff. The woman should have had 10 minutes to sit quietly and should not have ingested tobacco or caffeine for at least 30 minutes prior to measuring the blood pressure. She should be seated with her back against a chair, her legs uncrossed, and her forearm resting comfortably on a table. The diagnosis should be made on an average of two or more readings taken on two or more occasions. Out of office or home blood pressure readings are recommended for the confirmation of this diagnosis. If hypertension is diagnosed, the woman should be referred to a physician to establish a plan for care and monitoring.

Signs That Suggest Primary Versus Secondary Hypertension. Signs that suggest primary hypertension include family history, slowly increasing blood pressure over time, and lifestyle factors such as obesity, smoking, low level of physical activity, and excessive use of alcohol. Signs that suggest hypertension may be secondary include liable blood pressure, other systemic symptoms such as dizziness, snoring, muscle cramps or weakness, weight loss, edema, fatigue, or weakness. Disorders that are associated with secondary hypertension include hyperthyroidism, kidney disease, Cushing's syndrome, and medications such as cocaine, amphetamines, and NSAIDs.[20]

Atherosclerotic Cardiovascular Disease Risk. Screening for cardiovascular risks is a critical component of this evaluation because the benefit of pharmacologic management of hypertension is directly related to the risk for atherosclerotic cardiovascular disease (ASCVD). Pharmacologic treatment is recommended for persons with a systolic blood pressure of 130 mm Hg or higher or an average diastolic blood pressure of 80 mm Hg or higher.[20] Cardiovascular risk calculators are listed in the Resource at the end of this chapter.

White Coat Hypertension and Masked Hypertension. The 2017 guidelines include recommendations for screening individuals for white coat hypertension. White coat hypertension is the diagnosis for persons who have hypertension in an office setting but no hypertension at home. There are no data about the benefits or risks associated with treating persons with white coat hypertension.

Masked hypertension is not common but should be included in the differential diagnosis if the person reports a history of occasional hypertension but is normotensive during a primary care visit. Home blood pressure monitoring or ambulatory blood pressure monitoring can be helpful in establishing this diagnosis.

Laboratory Evaluation. If hypertension is detected, laboratory evaluation includes tests that will assess for complications of hypertension and the presence of comorbidities. Recommended laboratory evaluations include fasting blood glucose, thyroid indices, serum creatinine, lipid profile, serum sodium, potassium, and calcium, which may be part of a metabolic panel, and electrocardiogram.

Treatment of Primary Hypertension

Table 6-5 outlines the general management of persons with hypertension after the initial evaluation.[20] Many cases of primary hypertension are related to lifestyle, rather than underlying disease. These causes are directly modifiable through lifestyle changes such as weight loss, nutritional counseling for a low-sodium diet, exercise, smoking cessation, and moderation in alcohol consumption.[22,24,25] A weight loss of as little as 10 pounds may have a salutary effect on blood pressure. **Table 6-6** demonstrates the effect of lifestyle modification on blood pressure as reported by the JNC 7 and supported by the 2017 guidelines.[20,24] Achieving more than one modification has an independent effect on blood pressure so a combination of modifications can achieve better results.[25]

Table 6-5 Overview of Treatment and Recommended Follow-Up Following Initial Diagnosis of Hypertension

Diagnosis	Treatment and Recommended Follow-Up
Normotensive	Promote optimal lifestyle and repeat blood pressure evaluation annually
Elevated blood pressure	Non-pharmacologic lifestyle modifications and repeat evaluation in 3–6 months
Stage 1 hypertension with 10-year estimated ASCVD risk < 10%	Non-pharmacologic lifestyle modifications and repeat evaluation in 3–6 months
Stage 1 hypertension with 10-year estimated ASCVD risk > 10%	Non-pharmacologic lifestyle modifications and anti-hypertensive medication. Repeat evaluation in 1 month
White coat hypertension	If blood pressure is ≥ 130 mm Hg but <160 mm Hg systolic or > 80 mm Hg but < 100 mm Hg, HBPM or ABPM can be used to establish the diagnosis; if white coat hypertension is present, life style modification and annual monitoring with HBPM or ABPM to detect sustained hypertension
Masked hypertension	If office blood pressure is 120–129/80 mm Hg but the individual has a history of hypertension, HBPM or ABPM can be used to establish the diagnosis; if daytime HBPM or ABPM are ≥ 130/80 mm Hg, institute lifestyle modification and start antihypertensive medication

Abbreviations: ABPM, ambulatory blood pressure monitoring; ASCVD, atherosclerotic cardiovascular disease; HBPM, home blood pressure monitoring.

Based on Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension.* 2017. [Epub ahead of print]. doi:10.1016/j.jacc.2017.11.006.[20]

Table 6-6 Lifestyle Modifications to Prevent and Manage Hypertension[a]

Modification	Recommendation	Approximate SBP Reduction (Range)[b]
Weight reduction	Maintain normal body weight (BMI: 18.5–24.9 kg/m^2)	5–20 mm Hg/10 kg

Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with reduced saturated and total fat, and reduce dietary sodium to ≤ 100 mmol/day (2.4 g of sodium)	8–14 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 minutes per day, most days of the week)	4–9 mm Hg
Moderation of alcohol[c]	Men: No more than 1 oz of ethanol per day (2 drinks) Women: No more than 0.5 oz of ethanol per day (1 drink)	2–4 mm Hg

Abbreviations: BMI, body mass index; DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure.

[a] For overall cardiovascular risk reduction, stop smoking.

[b] The effects of implementing these modifications are dose and time dependent, and could be greater for a specific individual.

[c] Ethanol in a standard drink: 1 oz of ethanol = 12 oz beer, 5 oz wine, or 1.5 oz distilled spirits.

Based on Whelton PK, Carey RM, Aronow WS, et al. 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. Hypertension. 2017. [Epub ahead of print]. doi:10.1016/j.jacc.2017.11.006[20]; National High Blood Pressure Education Program. *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: Complete Report.* Bethesda, MD: National Heart, Lung, and Blood Institute; August 2004.[24]

In addition to lifestyle modifications, several categories of drugs can be prescribed to treat hypertension. Low-dose thiazide diuretics are an effective first-line choice; they have been demonstrated to reduce all-cause mortality, stroke, and cardiovascular disease.[26] Angiotensin-converting enzyme (ACE) inhibitors, calcium-channel blockers (CCBs), beta blockers, angiotensin II receptor blockers (ARB), and other drug categories are used either alone or in combination; ACE inhibitors have shown evidence of similar efficacy to thiazide diuretics, but are not superior and are more costly.[26] A meta-analysis of trials of antihypertensive drugs concluded that all classes of these medications had similar effectiveness in preventing coronary heart disease.[27] The choice of agent recommended for use may vary depending on the presence or absence of other risk factors or comorbidities. An algorithm for managing hypertension can be found in the JNC 7 and JNC 8 guidelines.[23,24]

Women who need pharmaceutical therapies are referred to a physician to initiate treatment. However, many midwives will provide care for women being treated or at risk for hypertension. Based on the practice setting, a midwife may consult with a specialist, refer the woman at the time of diagnosis to a specialist, or initiate an initial antihypertensive agent. If the initial pharmaceutical agent proves inadequate, as evidenced by the woman not meeting goal blood pressure in the algorithm, consultation and/or referral is warranted.

Dyslipidemia

Dyslipidemia—that is, elevated fat or cholesterol in the blood—is another major risk factor associated with cardiac disease, and often is preventable or modifiable. Low-density lipoprotein (LDL) has been used as a surrogate biomarker to assess for risk for cardiac

disease and is the major component of cholesterol, accounting for approximately 65% to 70% of total cholesterol. An elevation in LDL level is directly associated with the development of atherosclerotic plaques.

Specific risk factors for dyslipidemia include obesity, hypertension, diabetes, smoking, preexisting coronary heart disease, and a family history of early cardiovascular disease. Risk increases with age: For women, the clinically relevant increased risk is related to menopause, and age 55 years and older often is used as the point at which risk begins to spike upward. Conditions that increase the risk of dyslipidemia include diabetes; thyroid disease; kidney diseases including chronic renal failure and nephrotic syndrome; obstructive liver disease such as gallstones, hepatitis, and cirrhosis; and use of medications such as protease inhibitors, progestins, corticosteroids, and anabolic steroids. Data suggest that among women age 20 to 45 years, the majority have coronary heart disease, a coronary heart disease equivalent such as stroke, diabetes, or elevated fasting glucose level, or one or more coronary heart disease risk factors, although most do not receive screening.[28]

Screening for dyslipidemia in women of reproductive age is not standardized in the same manner as screening for hypertension. The American Academy of Family Physicians[29] and the American College of Obstetricians and Gynecologists (ACOG)[30] recommend screening low-risk women for dyslipidemia beginning at age 40 and 45 years, respectively, while the U.S. Preventive Services Task Force has no active recommendations governing whether or when to screen for dyslipidemia in adults. According to ACOG, earlier screening is warranted in women with risk factors such as recurrent preeclampsia and preterm birth before 37 weeks' gestation accompanied by preeclampsia.[30] Neither of the other authorities discusses high-risk factors that might warrant earlier screening, although in clinical practice screening is often performed if a woman has hypertension, obesity, diabetes, or other risk factors.[28]

Screening for dyslipidemia includes first conducting a global risk assessment of risk factors. For example, women with type 2 diabetes, type 1 diabetes for more than 15 years, two risk factors for cardiovascular disease, or metabolic syndrome should be considered to have a high or very high risk for atherosclerotic cardiovascular disease. The second step in screening is to obtain a complete lipid panel after an overnight fast. The panel will include blood values of LDL cholesterol, total cholesterol, and high-density lipoprotein (HDL) cholesterol. The third step is to calculate the 10-year risk for having a coronary event. Clinicians are advised to use an online calculator to predict 10-year risk for a first atherosclerotic cardiovascular disease (ASCVD) event.[31] This calculation incorporates medical history risks and the results of the lipid panel, then predicts 10-year risk of ASCVD and compares the individual's 10-year and lifetime risks to a hypothetical individual with optimal characteristics. Links to online calculators are included in the Resources section at the end of this chapter.

When high cholesterol levels are found, counseling includes making diet changes to decrease total and dietary fat to between 25% and 35% of total calories, adding dietary fiber, stopping smoking, and increasing exercise levels. Medication therapy can be deferred while a trial of healthy lifestyle changes is undertaken, as long as there is no family history suggestive of genetic predisposition to coronary artery disease and the LDL cholesterol level is less than 160 mg/dL for women without other cardiac risk factors. Determining which woman needs

intervention and how her progress should be followed may be an indication for consultation or referral to a specialist. Pharmacologic therapy is instituted based on LDL level and risk profile.

The most widely accepted guidelines for the management of dyslipidemia are those established by the American College of Cardiology and the American Heart Association.[32] The most recent guidelines, released in 2013, focus on an algorithm for appropriate statin use. Liberal initiation of statins is recommended as the primary mode of treatment for individuals with clinical indications of atherosclerotic cardiovascular disease, including LDL cholesterol levels of 190 mg/dL or higher or conditions such as diabetes. The guidelines recommend the use of other products as adjunctive therapy in rare cases such as statin resistance cases or in individuals unable to tolerate statins.[32] According to the American College of Cardiology/American Heart Association, the strongest evidence for the use of statins are for the following indications[32]:

- Primary prevention of atherosclerotic cardiovascular disease in individuals with LDL cholesterol ≥ 190 mg/dL
- Primary prevention of atherosclerotic cardiovascular disease in individuals with diabetes age 40–75 years with LDL cholesterol levels of 70–189 mg/dL
- Primary prevention of atherosclerotic cardiovascular disease in individuals without diabetes with an estimated 10-year ASCVD risk ≥ 7.5%, with LDL cholesterol levels of 70–189 mg/dL, and age 40–75 years
- Secondary prevention of additional morbidity and mortality in individuals with clinical atherosclerotic cardiovascular disease

Statins are categorized by how well they lower LDL cholesterol on average. **Table 6-7** categorizes the common statins as either high, moderate, or low intensity to be consistent with the terminology used in the current guidelines.[32]

Table 6-7 High-, Moderate-, and Low-Intensity Statin Therapies[a]

High Intensity (Daily Dosage Lowers LDL-C by Average of ≥ 50%)	Moderate Intensity (Daily Dosage Lowers LDL-C by Average of 30–50%)	Low Intensity (Daily Dosage Lowers LDL-C by Average of < 30%)
Statins and Doses Approved by the FDA and Tested in RCTs		
Atorvastatin (Lipitor), 40 mg[b] to 80 mg	Atorvastatin (Lipitor), 10 (20) mg	Lovastatin (Mevacor), 20 mg
Rosuvastatin (Crestor), 20 (40) mg	Rosuvastatin (Crestor), (5) 10 mg	Pravastatin (Pravachol), 10–20 mg
	Simvastatin (Zocor), 20–40 mg[c]	
	Pravastatin (Pravachol), 40 (80) mg	
	Lovastatin (Mevacor), 40 mg	
	Fluvastatin (Lescol), 40 mg 2 times daily	
Statins and Doses Approved by the FDA But Not Tested in RCTs		

	Fluvastatin XL (Lescol XL), 80 mg	Simvastatin (Zocor), 10 mg
	Pitavastatin (Livalo), 2–4 mg	Fluvastatin (Lescol), 20–40 mg
		Pitavastatin (Livalo), 1 mg

Abbreviations: FDA, U.S. Food and Drug Administration; LDL-C, low-density lipoprotein cholesterol; RCT, randomized controlled trial.

[a] Individual responses to statin therapy varied in the RCTs and should be expected to vary in clinical practice. There might be a biological basis for less than average response.

[b] Evidence from one RCT only. Down-titration was initiated if the participant was unable to tolerate atorvastatin 80 mg in the IDEAL (Incremental Decrease Through Aggressive Lipid Lowering) study.

[c] Although simvastatin 80 mg was evaluated in RCTs, initiation of simvastatin 80 mg or titration to 80 mg is not recommended by the FDA because of the increased risk of myopathy, including rhabdomyolysis.

Modified with permission from Stone NJ, Robinson JG, Lichtenstein AH, et al. ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;63:2889-2934.[32]

Individuals who will benefit from clinical use of statin therapy, as well as the types of therapy, are found in **Figure 6-1**. Some midwives may consult or refer a woman with dyslipidemia to a specialist upon discovery of the condition, whereas others may initiate statin therapy but will consult or refer if the response is inadequate as measured by serum cholesterol levels.

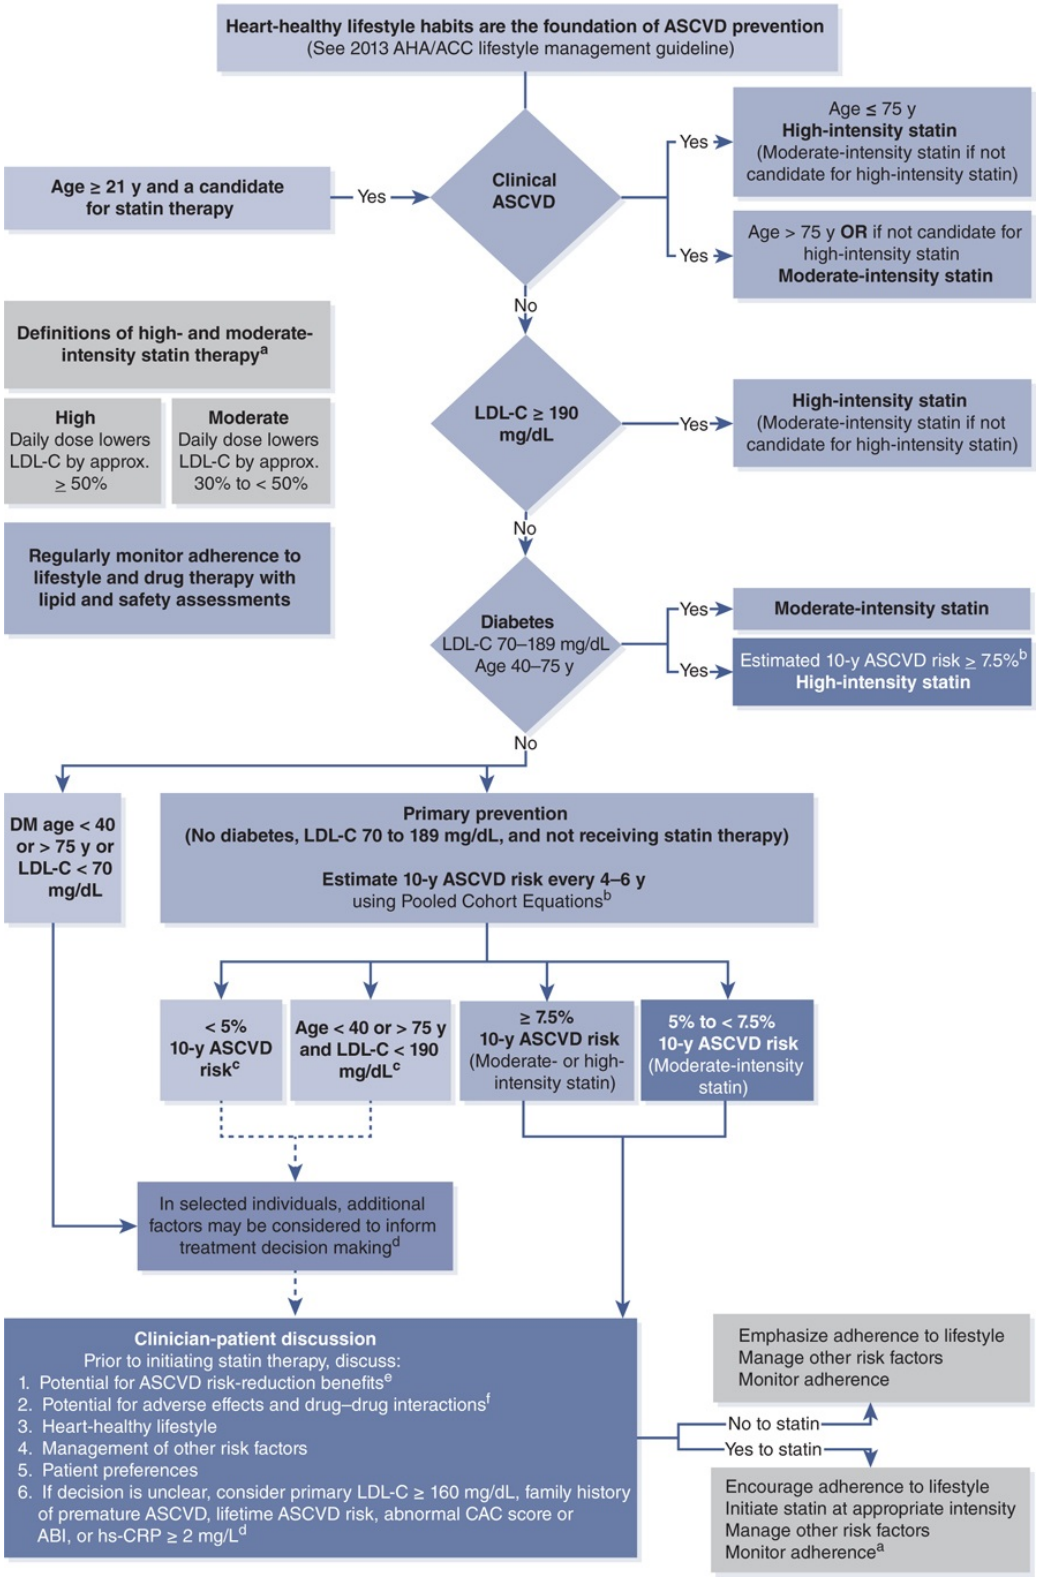

Figure 6-1 American College of Cardiology/American Heart Association blood cholesterol guideline.

Abbreviations: ABI, ankle-brachial index; ASCVD, atherosclerotic cardiovascular disease; CAC, coronary artery calcium; DM, diabetes mellitus; hs-CRP, high-sensitivity C-reactive protein; LDL-C, low-density lipoprotein cholesterol; RCT, randomized controlled trial.

[a] Percent reduction in LDL-C can be used as an indication of response and adherence to therapy, but is not in itself a treatment goal.

[b] The Pooled Cohort Equations can be used to estimate 10-year ASCVD risk in individuals with and without diabetes. The estimator within this application should be used to inform decision making for primary prevention in patients not on a statin.

[c] Consider a moderate-intensity statin as more appropriate therapy in low-risk individuals.

[d] For those individuals in whom a risk assessment is uncertain, consider factors such as primary LDL-C ≥ 160 mg/dL or other evidence of genetic hyperlipidemias; family history of premature ASCVD with onset before 55 years of age in a first-degree male relative or before 65 years of age in a first-degree female relative; hs-CRP ≥> 2 mg/L; CAC score ≥ 300 Agatston units or ≥ 75th percentile for age, sex, and ethnicity; ABI < 0.9; or lifetime risk of ASCVD. Additional factors that may aid in individual risk assessment may be identified in the future.

[e] Potential ASCVD risk-reduction benefits. The absolute reduction in ASCVD events from moderate- or high-intensity statin therapy can be approximated by multiplying the estimated 10-year ASCVD risk by the anticipated relative-risk reduction from the intensity of statin initiated (approximately 30% for a moderate-intensity statin or approximately 45% for a high-intensity statin). The net ASCVD risk-reduction benefit is estimated from the number of potential ASCVD events prevented with a statin, compared to the number of potential excess adverse effects.

[f] Potential adverse effects. The excess risk of diabetes is the main consideration in approximately 0.1 excess case per 100 individuals treated with a moderate-intensity statin for 1 year and approximately 0.3 excess case per 100 individuals treated with a high-intensity statin for 1 year. In RCTs, both statin-treated and placebo-treated participants experienced the same rate of muscle symptoms. The actual rate of statin-related muscle symptoms in the clinical population is unclear. Muscle symptoms attributed to statin therapy should be evaluated.

ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;63:2889-2934.[31]

Respiratory Conditions

Upper Respiratory Infections

Upper respiratory infections (URIs) include the common cold, rhinosinusitis, influenza, and pharyngitis. Commonly viral in nature, nonspecific URIs and influenza are a frequent reason for calls to healthcare providers, with individuals often asking for antibiotics that will not cure the problem. Although rates of inappropriate prescribing have decreased, rates of overtreatment remain high.[33] Both overtreatment and inappropriate treatment have led to a rapid increase in the prevalence of infections with drug-resistant *Streptococcus pneumoniae* and *Staphylococcus aureus*, which are the two most common bacterial respiratory pathogens. *S. pneumoniae* is increasingly resistant to penicillin, amoxicillin/clavulanate, and ceftriaxone, while more than 50% of *S. aureus* isolates have been found to be resistant to methicillin in antibiotic surveillance systems.[34]

Many URIs can be avoided through the use of simple hygiene techniques, most particularly the practice of hand washing. The use of antibacterial soaps and environmental sprays usually is not necessary in the home, but has not been linked to adverse ecological events. Hand sanitizers have become useful items in public areas, especially when respiratory infections are prevalent.

The diagnosis of nonspecific URI is made based on the presence of nasal congestion and a clear, white, or yellow/green discharge, as well as sore throat, muscle aches, headache, and cough. The symptoms of colds and influenza overlap, although high fever, profound malaise, and dry cough are more typical of the “flu” than of a cold. Symptomatic management may reduce the severity of symptoms, although many interventions commonly implemented lack evidence of effectiveness. Treatments include rest, increased fluids, saline gargle or spray, and a variety of medications. Pharmaceuticals are best targeted to specific symptoms, such as dextromethorphan (Delsym) for coughs; therefore, combination drugs are not advised. Antibiotics are not indicated for treatment of individuals with nonspecific URI or influenza.[35]

Ipratropium bromide (Atrovent), an anticholinergic nasal spray, can be used if needed to relieve rhinorrhea, sneezing, and congestion. Initial use consists of two sprays in each nostril, three to four times daily.[36] Antihistamines may provide limited relief in the first few days after the onset of a URI.[37] Intranasal corticosteroids have not shown any benefit for URIs, but are not harmful and may be continued if being used for another condition.[38] Regardless of pharmaceutical treatments, resolution of symptoms should be complete within a week.

A bacterial cause for URI should be suspected when the symptoms persist or worsen after 8 to 10 days; when maxillofacial pain is present (especially if only one side of the face is affected); when the symptoms over the first 3 to 4 days are severe; when symptoms are associated with a fever higher than 39°C (102.2°F); when purulent discharge is present; or when symptoms worsen after a viral infection had appeared to be resolving. If antibiotic therapy is needed, the narrowest-spectrum drug effective against *S. pneumoniae* and *Haemophilus influenzae* should be used.

Common Cold

The common cold is a self-limited syndrome that can be caused by many different viruses. This type of mild URI is the most frequent illness experienced by adults and children in industrialized nations. Symptoms include varying patterns of nasal discharge, headache, sore throat, sore muscles, cough, or sneezing. The common cold is usually spread via droplets and hard-surface contamination. The incubation period is 24 to 72 hours, and the period of infectivity starts approximately on the second day of illness and peaks on the third day of illness. Nevertheless, viruses that cause the common cold can be infective for several days. The initial differential diagnosis is allergic or bacterial rhinitis, bacterial pharyngitis, pertussis, and influenza. Complications associated with the common cold include rhinosinusitis, lower respiratory tract infections, exacerbation of asthma, and bronchitis.

Rhinosinusitis

When an acute URI has spread into the sinus cavities, the term *rhinosinusitis* usually is preferred to the older term *sinusitis*. A green or yellow nasal discharge commonly is found in addition to pain and pressure over the affected sinus. Other symptoms may include a toothache near the affected sinus, fever, and a cough that worsens when lying down. More than 95% of these infections are viral.[39] Acute rhinosinusitis lasts less than 4 weeks, and most such infections resolve spontaneously.[39] Although fewer cases of rhinosinusitis are bacterial in origin, overuse of antibiotics is common: One study found that these medications were prescribed in more than 80% of rhinosinusitis episodes.[39] Three clinical scenarios suggest a bacterial infection: (1) persistent symptoms for more than 10 days without improvement; (2) severe onset with a high fever of at least 39°C (102.2°F) and purulent nasal discharge for 3 or more days beginning with the onset of symptoms; or (3) “double-sickening,” in which viral symptoms begin to improve but then suddenly worsen near the end of the first week.[35]

Therapy for rhinosinusitis includes supportive management with over-the-counter (OTC) decongestants, analgesics, and antipyretics. As with the common cold, antihistamines should not be used unless the congestion has an allergic component. When symptoms of a bacterial infection or super-infection are present, then antibiotics should be initiated. Ampicillin–clavulanate (Augmentin) or doxycycline (Vibramycin) is the preferred initial regimen. Fluoroquinolones can be used as an alternative; however, azithromycin (Zithromax), trimethoprim–sulfamethoxazole (TMP-SMX; Bactrim), and cephalosporins are not recommended due to the increased risk of resistance to these drugs.[35] When symptoms persist for more than 12 weeks, referral to a specialist is warranted for evaluation of possible chronic rhinosinusitis or another underlying condition.[39]

Influenza

The onset of viral influenza is abrupt, marked by fever, rhinitis, cough, sore throat, headache, muscle pain, and general malaise. Most symptoms will resolve in a week or less, although malaise and tiredness may persist. Influenza should be suspected as the cause of URI during the flu season, which typically begins in October and lasts through April. Herd immunity achieved by widespread vaccination is the best protection against influenza outbreaks.

Vaccines for the seasonal flu types anticipated by the Centers for Disease Control and Prevention (CDC) become available in early fall and are recommended for all persons. Recommendations for vaccine formulations may change yearly depending on the prevalence and severity of the viruses in circulation and the availability and effectiveness of current vaccines. For example, the live attenuated influenza vaccine (LAIV), administered intranasally, was not recommended for use in the 2016–2017 flu season; the Advisory Committee on Immunization Practices has issued an interim recommendation that this vaccine not be used because it has been shown to have low effectiveness over the last two influenza seasons.[40] Detailed recommendations for flu vaccines are presented in the *Health Promotion Across the Lifespan* chapter. Individuals at greater risk of severe complications of influenza are listed in **Table 6-8**.[41]

Table 6-8	**Individuals at Increased Risk of Complications of Influenza**
Persons age ≥ 50 years	
Persons with chronic disease:	
Pulmonary (including asthma)	
Cardiovascular (except hypertension)	
Renal	
Hepatic	
Neurologic	
Hematologic	
Metabolic disorders (including diabetes mellitus)	
Persons who are immunosuppressed (caused by medications or HIV)	
Women who are or may be pregnant during the influenza season	
Children 6 months to 18 years receiving long-term aspirin therapy who might be at risk for Reye's syndrome after influenza virus infection	
Residents of nursing homes and other chronic care facilities	
American Indians/Alaska natives	
Persons with BMI > 40 kg/m^2	
Healthcare personnel	
Household contacts and caregivers of the following:	
Children age < 5 years	
Adults age ≥ 50 years	
Children age < 6 months	
Persons with conditions that increase risk for severe complications of influenza	

Abbreviations: BMI, body mass index; HIV, human immunodeficiency virus.

Reproduced with permission from Centers for Disease Control and Prevention. People at high risk of developing flu-related complications. 2016. Available at: https://www.cdc.gov/flu/about/disease/high_risk.htm. Accessed March 13, 2017.[41]

The CDC recommends the use of the neuraminidase inhibitors oseltamivir (Tamiflu) or zanamivir (Relenza) to treat influenza.[42] Treatment of infections suspected of being influenza within 48 hours of the onset of symptoms may shorten the duration of infection by

approximately one day. Without pharmacologic treatment, in healthy adults, influenza is a self-limiting disease and may be best treated with rest and supportive therapy.

Pharyngitis

Approximately 5% to 15% of cases of sore throat are caused by group A beta-hemolytic *Streptococcus* (GAS); the remainder are primarily viral in origin and require only supportive care while symptoms resolve. Testing for GAS is not necessary when symptoms—cough, runny nose, oral sores, and hoarseness—clearly indicate a viral infection. In contrast, tonsillar exudate, tender anterior cervical lymph nodes, fever, and lack of a cough suggest a bacterial infection. Either a rapid antigen detection test or culture can be performed if symptoms do not exclude GAS. Follow-up culture after a negative rapid antigen detection test is no longer recommended in adults.[43]

Penicillin and amoxicillin regimens lasting 10 days are the most appropriate first-line treatments for GAS. First-generation cephalosporins, clindamycin (Cleocin), clarithromycin (Biaxin), or azithromycin (Zithromax), are all acceptable alternatives when penicillin allergy exists. An analgesic or antipyretic can be used for supportive therapy; corticosteroids are not recommended. It is not necessary to treat household contacts.[43]

Bronchitis

Infections of the lower respiratory tract limited to the trachea and bronchi are termed *bronchitis*; they can appear as an inflammatory response to an otherwise uncomplicated URI. In healthy women of reproductive age, acute bronchitis is typically a viral syndrome of low-grade fever, malaise, fatigue, sore throat, chest pain, and cough. The cough may be productive or nonproductive. The cough of bronchitis can be differentiated from the cough of the common cold when it persists more than 5 days. Smoking, exposure to irritating fumes in the environment, and gastric reflux that irritates the bronchi can also precipitate acute bronchitis. Long-term exposure to smoking or environmental pollutants can lead to chronic bronchitis. On auscultation, areas of the lung other than over the bronchi should not have abnormal findings; a chest X ray, if performed, should not show infiltrates. Worsening chest pain with shortness of breath or pain on inspiration suggests pneumonia.

In most cases, the infection and the cough will resolve within 1 to 2 weeks with supportive therapy. If cough is persistent after the primary infection has resolved and wheezing is noted, the use of an albuterol inhaler may provide relief.[44] If an inhaler is prescribed, the directions should be for two puffs every 4 to 6 hours as needed to relieve symptoms. Asthma should be considered as an alternative diagnosis.

Antibiotics are not useful in the case of viral bronchitis, but under certain circumstances suspected bacterial infections of the bronchi may require antibiotic therapy. Antibiotics should be avoided in healthy adults with moderate symptoms; their potential benefit is outweighed in most cases by the potential for increased resistance and the expense of therapy.[45,46]

If the diagnosis is unclear, or if symptoms persist and worsen, both pneumonia and pertussis should be ruled out. Signs and symptoms that indicate the diagnosis is pneumonia include

temperature greater than or equal to 38°C (100.4°F), tachypnea at more than 24 breaths per minute, tachycardia at more than 100 beats per minute, rales or decreased breath sounds. and symptoms that develop quickly.[47] Women with symptoms suggestive of pneumonia warrant referral to a specialist for evaluation.

Community-Acquired Pneumonia

Together, influenza and pneumonia are the leading infectious cause of death in the United States and the eighth most frequent cause of death overall.[17] Predisposing factors for pneumonia include damage to the cilia of the respiratory tract from chronic cough, viral infections, or smoking. The common infecting organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Staphylococcus aureus*, and a variety of viruses, most commonly influenza. Because bacterial causes of community-acquired pneumonia predominate, antibiotic therapy should be instituted promptly when a diagnosis is made. Risk factors for community-acquired pneumonia include age older than 65 years, underweight or BMI less than 19 mm/kg^2, smoking, excessive alcohol intake, decreased ciliary activity, prior episodes of pneumonia or chronic bronchitis, chronic obstructive pulmonary disease, use of antihistamines, immunosuppression, and chronic illnesses.[48,49]

The onset of symptoms with community-acquired pneumonia is usually abrupt, with fatigue, cough, difficulty breathing, chills/sweats, anorexia, headache, and chest pain being the most common. Fever of 38°C (100.4°F) or higher, tachycardia, tachypnea, rales, and lung consolidation can be found on examination. When the cause is bacterial, high fever and a productive cough are more likely, whereas viral causes produce a more generalized malaise. Chest X ray is indicated to confirm the diagnosis and to identify underlying complications. Microbiologic testing to confirm the pathogen is not routinely recommended before empiric therapy is initiated,[48] but at least one expert has recently argued that this practice runs counter to the need for better targeting of antibiotic therapy to reduce risk of resistance in common pathogens.[50,51]

Outpatient versus inpatient treatment of women with community-acquired pneumonia is a decision with significant consequences in terms of treatment modalities, testing schemes, and costs. While uncomplicated pneumonia should be treated promptly with antibiotics and can safely be managed on an outpatient basis in healthy adults, consultation with and likely referral to a specialist are necessary for women with suspected pneumonia. Recommendations for pneumococcal vaccines can be found in the *Health Promotion Across the Lifespan* chapter.

Pertussis

Bordetella pertussis is an increasingly important respiratory pathogen; 20,752 cases of this infection were diagnosed in the United States in 2015 after a peak of 32,971 cases the previous year, and the CDC suggests that many cases go unreported.[52] Pertussis affects the ability to clear the respiratory tract by paralyzing the cilia lining the respiratory tract and causing inflammation as well as by directly invading the alveoli.[53] The incubation period is approximately 7 to 10 days, but symptoms can first occur as distant in time as 6 weeks

following exposure. Clinically, the first symptoms resemble a mild URI, with little temperature elevation. Although pertussis is milder in adults than in infants or young children, it can persist with an increasingly violent cough over several weeks. **Table 6-9** provides a description of the stages of the disease.[53]

Table 6-9 Stages of Pertussis (Whooping Cough)

Stage	Duration	Symptoms
Catarrhal	1–2 weeks	Cough, runny nose, low-grade fever, sneezing
Paroxysmal	1–6 weeks	Episodes of rapid coughing 15 or more times per day, ending with a long inspiratory gasp and high-pitched "whooping" sound, occurring more often at night, accompanied by possible vomiting, exhaustion
Recovery	Weeks to months	Slowly resolving symptoms: cough disappears within 2–3 weeks, may return with subsequent respiratory illnesses

Based on Hamborsky J, Kroger A, Wolfe S. Pertussis. In: Hamborsky J, Kroger A, Wolfe S, eds. *Epidemiology and Prevention of Vaccine-Preventable Diseases.* 13th ed. Washington, DC: Public Health Foundation; 2015. Available at: https://www.cdc.gov/vaccines/pubs/pinkbook/pert.html. Accessed May 13, 2017.[53]

Common complications of untreated pertussis in adults include rib fracture, pneumothorax, superimposed bacterial pneumonia, and urinary incontinence. Other risks that are less common include dehydration, epistaxis, hernia, and—rarely—encephalopathy, pneumothorax, rectal prolapse, subdural hematoma, and seizure.[53]

In addition to vaccinating infants and children, vaccination against pertussis with the tetanus/diphtheria/acellular pertussis (Tdap) combination vaccine among adults is an effective measure to control the spread of this disease. The action of vaccinating others around the child often is called "cocooning," and is accomplished by administering the Tdap vaccine to all adults who have close interaction with newborns. Recommendations regarding the pertussis vaccine for women of all ages are described in detail in the *Health Promotion Across the Lifespan* chapter.

Therapy for pertussis includes a macrolide antibiotic; the original recommendation for erythromycin was expanded to include azithromycin (Zithromax) and clarithromycin (Biaxin) as these macrolides are better tolerated. TMP-SMX (Bactrim) can also be used for therapy. Post-exposure prophylaxis with the same drugs is recommended for all close contacts of a pertussis case, for individuals at high risk of severe disease (newborns, women in the third trimester, and individuals with preexisting conditions such as moderate to severe asthma or immunosuppression that could be exacerbated by infection), and for persons who have close contact with those at risk of severe disease.[54] It is not known whether post-exposure vaccination has any benefit.[53]

Asthma

Asthma is a chronic inflammation of the airways associated with intermittent worsening of

symptoms; reversible obstruction from bronchospasm, edema, and mucus production; and hyper-responsiveness to stimuli. An individual's innate immunity, genetics, and environmental exposures all play a role in the development of this chronic disease. The prevalence of asthma in the United States is increasing, with this condition affecting almost 10% of all women.[55] Among the approximately 19 million women with asthma, those living in poverty have the highest risk.[55]

Signs and symptoms suggestive of asthma are listed in **Table 6-10**.[56] On examination, wheezing when breathing normally, prolonged expiratory phase, use of accessory muscles, increased nasal swelling, secretions or polyps, and evidence of atopy all increase the likelihood of an asthma diagnosis. Pulmonary function testing is required for diagnosis. The differential diagnosis in adults includes chronic obstructive pulmonary disease, vocal cord dysfunction, congestive heart failure, medication-related cough, pulmonary embolism, and gastroesophageal reflux disease, among others.[56] Midwives practicing in areas of high asthma frequency may keep flow meters in their offices either to assist in the presumptive diagnosis of asthma or to assess lung function when women with asthma present or are symptomatic. Four classes of asthma are distinguished based on severity of disease, as shown in **Table 6-11**.[57]

Table 6-10 Characteristic Signs and Symptoms of Asthma

The presence of one or more of these symptoms is an indication for evaluation:
Wheezing (not required for diagnosis)
History of:
Persistent cough (particularly at night)
Recurrent wheezing
Recurrent difficulty in breathing
Recurrent chest tightness
Symptoms occur or are worsened by:
Exercise
Viral infection
Inhalant allergens such as dust mites, mold, pollen, animals with fur
Irritants to lung tissue such as smoke or airborne chemicals
Changes in weather
Strong emotional expression (laughing or crying hard)
Stress
Menstrual cycles
Symptoms occur or worsen at night, awakening the individual

Modified with permission from National Asthma Education and Prevention Program. *Expert Panel Report: Guidelines for the Diagnosis and Management of Asthma (EPR-3).* Bethesda, MD: National Heart, Lung, and Blood Institute; 2007.[56]

Table 6-11 Classification of Asthma

Disease Severity	Daytime Symptoms	Nighttime Symptoms	PEF or FEV	Interference with Normal Activity	Use of Short-Acting Medication	Asthma Exacerbation frequency[a]
Mild intermittent	≤ 2 days/week	≤ 2 nights/ month	> 80%	None	≤ 2 days/week	0–1/year
Persistent mild	> 2 days/week but not daily	> 2 nights/ month	> 80%	Minor	> 2 days/week but not daily and not more than 1 time/day	≥ 2/year
Persistent moderate	Daily	> 1 night/week but not nightly	> 60 and < 80%	Some	Daily	≥ 2/year
Persistent severe	Continual	Frequent	≤ 60%	Extremely limited	Several times/ day	≥ 2/year

Abbreviations: FEV, forced expiratory volume; PEF, peak expiratory flow.

[a] Data are insufficient to link frequency of exacerbations to different levels of severity. Generally, more frequent and intense exacerbations are an indication of increasing severity. Persons with ≥ 2 exacerbations per year may be considered to have persistent asthma even in the absence of impairment levels consistent with persistent asthma.

Modified with permission from National Heart, Lung, and Blood Institute. Asthma care quick reference. 2012. Available at: https://www.nhlbi.nih.gov/files/docs/guidelines/asthma_qrg.pdf. Accessed March 13, 2017.[57]

Important components of the management of asthma include patient education, management of environmental factors and comorbidities that worsen symptoms, and use of medication. The key to control of asthma and prevention of worsening of this condition is inclusion of the woman in decisions about her care, awareness of environmental triggers and the need to minimize exposure when possible, and knowledge of the role that other health problems play in asthma management.[56]

Medication management is based on a stepwise approach.[57] Intermittent symptoms of asthma (occurring fewer than 2 days per week, disturbing nighttime rest fewer than 2 days per month, not interfering with activities of daily living, and with one or fewer exacerbations per year) can be managed with short-acting beta-agonists such as albuterol sulfate (Proventil) on an as-needed basis. When a rescue inhaler is needed on more than 2 days per week, persistent asthma should be considered.

Anyone with persistent asthmatic symptoms needs to be on daily medication. Inadequate treatment limits physical activity, decreases pulmonary function, and increases the risk of recurrent attacks. The choice of medications is based on both the severity and the persistence of symptoms. The main classes of asthma drugs for long-term maintenance include inhaled corticosteroids, immunomodulators, leukotriene receptor antagonists, long-acting beta-agonists, 5-lipoxygenase inhibitors, mast cell mediators, methylxanthines, and combination drugs. The preferred agents for all patients with asthma, regardless of stage, are inhaled corticosteroids because they reduce inflammation and are theorized to minimize the risk of airway remodeling.

Women with newly diagnosed asthma should be evaluated in consultation with or by referral to a specialist experienced in respiratory care. Individuals with known mild intermittent, persistent mild, or persistent moderate asthma can be cared for by a midwife for primary care

and monitoring. However, consultation with an asthma specialist is warranted if a woman requires more than medium-dose inhaled corticosteroids to achieve control (Stage 4 or higher) or if she has unstable asthma.[57]

Tuberculosis

Although the rate of tuberculosis (TB) infection has been declining in the United States for the last 20 years, nearly 10,000 cases were reported in 2015.[58] Asians and Pacific Islander/Native Hawaiians are disproportionally affected by this infection.[58] Notably, tuberculosis among individuals born outside of the United States accounts for more than 66% of all diagnosed cases.[58] Poverty, lack of education, and positive status of human immunodeficiency virus (HIV) are associated with increased risk of acquiring the infection. Even though midwives may not provide first-line management for women with tuberculosis, populations for whom midwives often provide care may be at high risk for TB. Factors that confer a high risk for contracting TB infection are listed in **Table 6-12**.

Table 6-12 **Persons at Higher Risk for Exposure to and/or Infection with *M. tuberculosis***

Close contact with a person who has known or suspected active TB
Foreign-born persons from areas with high rates of TB (e.g., Africa, Asia, Eastern Europe, Latin America and Russia)
Persons who work or reside with people at high risk for TB (e.g., correctional facilities, long-term care facilities, homeless shelters)
Healthcare workers who serve individuals who are at increased risk for TB
Active substance use, especially intravenous drug use
Immune suppression: HIV/AIDS, diabetes mellitus, transplant recipients, chronic steroid treatment, renal disease, cancer of head, neck, and/or lung
Intestinal bypass or gastrectomy procedures

Abbreviations: HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; TB, tuberculosis.

Modified with permission from Centers for Disease Control and Prevention. *Core Curriculum on Tuberculosis: What the Clinician Should Know.* 6th ed. Atlanta, GA: Centers for Disease Control and Prevention; 2013. Available at: https://www.cdc.gov/tb/education/corecurr/pdf/corecurr_all.pdf. Accessed April 29, 2017.[59]

Transmission

The tuberculosis bacterium is spread by droplet formation or aerosolization, so casual contacts of individuals with active disease are at minimal risk of becoming infected. Conversely, close family members and those in close daily contact with the infected individual are most likely to have been exposed. Because *Mycobacterium tuberculosis* does not produce toxins, infection with this pathogen does not induce an immediate host response. Cellular immune response and a positive tuberculin skin test occur 2 to 12 weeks after acquisition of the bacterium. Symptoms may include generalized malaise and fatigue, night sweats, weight loss, fever, and a productive cough with or without hemoptysis. Pleuritic pain may develop, and on examination, crepitus and rales may be heard.[58]

Screening for Tuberculosis

The purpose of screening for tuberculosis is to detect individuals who have inactive disease as well as those who have recently been infected. The test most commonly used for this purpose is the intradermal tuberculin screening test, formerly known as PPD (purified protein derivative).[58] This test is read 48 to 72 hours after the tuberculin is injected in the subcuticular area of the forearm. Results are assessed by the degree of the diameter of a palpable swelling (induration), measured in millimeters, excluding erythema. The amount of induration required for a positive reading is affected by several factors, listed in **Table 6-13**.[59] A positive intradermal tuberculin screening test indicates the woman has disease that may or may not be currently active. Women with latent tuberculosis, who are not contagious and do not have TB disease, may have a positive TB screen.[59] The intradermal tuberculin screening test does not need to be repeated for anyone with a documented prior positive result.

Table 6-13 **Classification of the Tuberculin Skin Test Reaction**[a]

Induration ≥ 5 mm is considered positive in:	Induration ≥ 10 mm is considered positive in:	Induration ≥ 15 mm is considered positive in:
HIV-infected persons A recent contact of a person with infectious TB disease Persons with fibrotic changes on chest X ray Persons with organ transplants Persons who are immunosuppressed for other reasons	Persons recently in the United States (< 5 years) from high-prevalence countries (Asia, Africa, Eastern Europe, Latin America, Russia) Injection drug users Residents and employees of high-risk congregate settings Mycobacteriology laboratory personnel Persons with clinical conditions that place them at high risk (diabetes, silicosis, severe kidney disease, certain types of cancer, and some intestinal conditions) Children < 5 years of age Infants, children, and adolescents exposed to adults in high-risk categories	Any person with no known risk factors for TB

Abbreviations: HIV, human immunodeficiency virus; TB, tuberculosis.

[a] Targeted skin testing programs should be conducted only among high-risk groups.

Modified with permission from Centers for Disease Control and Prevention. *Core Curriculum on Tuberculosis: What the Clinician Should Know.* 6th ed. Atlanta, GA: Centers for Disease Control and Prevention; 2013. Available at: https://www.cdc.gov/tb/education/corecurr/pdf/corecurr_all.pdf. Accessed April 29, 2017.[59]

Alternatively, two blood tests that may be used to screen for TB in individuals who have received the bacillus Calmette-Guerin (BCG) vaccine or who are unable to return to have the intradermal tuberculin screening test results read, such as women screened in an emergency department. Many women born outside of the United States and some U.S.-born women may have received a BCG vaccine in childhood to prevent tuberculosis infection; this test may result in a permanent positive intradermal tuberculin screening test, necessitating other methods of screening.

When the intradermal tuberculin screening test or TB blood test is positive, the woman may

have active TB disease or latent tuberculosis. Women with latent tuberculosis are not contagious and do not have TB disease.[59] Chest X ray is used to rule out pulmonary tuberculosis for individuals with a positive intradermal tuberculin screening test or TB blood test, though sputum culture is required to confirm a diagnosis of active TB disease.[58,59]

Sputum cultures should be performed when there is clinical suspicion of active tuberculosis. A delay as long as 2 weeks may occur before results become available, but presumptive management should continue, even though the diagnosis is not final without the confirmation of cultures. A smear from the sample can be evaluated for the presence of mycobacteria by acid-fast or fluorescent stain. Even when the stain is negative, the sputum sample should be sent for culture.[58]

Any woman suspected of latent tuberculosis or active TB infection should be promptly referred to a specialist for ongoing care. In some settings, it may be appropriate for the midwife to order the chest X ray or other testing to expedite treatment while the woman is waiting for an appointment with a physician.

Treatment

To prevent progression to active TB disease, most women who have been diagnosed with latent tuberculosis should be treated. Several treatment regimens are considered acceptable for the treatment of latent TB that differ in the agent used and duration of treatment, which ranges from 3 to 9 months.[58,59] Active disease is treated with one of several multidrug combinations, which are administered over 6 to 9 months of uninterrupted therapy.[58,59]

Teaching includes the benefits and risks of long-term therapy, the importance of adherence, and side effects. At least monthly, the woman should be assessed for adherence to the medication regimen, signs and symptoms of active disease, and symptoms of hepatitis.[59] Even though other healthcare providers will be responsible for prescribing and monitoring tuberculosis treatment regimens, midwives need to be cognizant of appropriate management to promote completion of therapy and monitoring.

Gastrointestinal Disorders and Abdominal Pain

Stomach aches and pains, diarrhea and constipation, and bloating are all common symptoms reported by women.[60] As part of the history for any woman of childbearing age, last menstrual period and potential pregnancy risk are routinely assessed. Ensuring that women of childbearing age are not pregnant is an essential first step whenever abdominal symptoms are present because diagnosis and management can be influenced by this condition. This section focuses on general gastrointestinal health concerns common to all women. Complications that occur during pregnancy and produce abdominal symptoms are addressed in the *Pregnancy-Related Conditions* and *Medical Complications in Pregnancy* chapters. Similarly, gynecologic concerns are addressed in the *Menstrual Cycle Abnormalities* and *Gynecologic Disorders* chapters.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the more severe and persistent form of gastroesophageal reflux, caused by involuntary relaxation of the sphincter muscle separating the esophagus and the stomach. This condition is responsible for more than 8 million office visits annually, and is the most common gastrointestinal diagnosis.[60] When gastric reflux occurs more than twice a week, GERD is diagnosed. GERD produces symptoms of heartburn that worsen with meals, bending over, and lying down. Other, less easily recognizable symptoms include an asthma-like wheeze, cough, laryngitis, and chest pain. Persistent severe disease may produce complications such as injury to the epithelium of the esophagus (Barrett's esophagus), stricture formation, and adenocarcinoma. Hiatal hernia—that is, separation of the diaphragm that allows the sphincter and upper portion of the stomach to penetrate into the chest cavity—is common in healthy older adults and can contribute to the symptoms of GERD. Obesity and smoking influence the development of GERD, as can pregnancy. *Helicobacter pylori* infection, the dominant cause of gastroduodenal ulcers, does not appear to have an effect on the occurrence of GERD.[61]

Therapy for GERD includes weight reduction, consumption of a low-fat diet, and avoidance of triggers such as caffeine, tobacco, and spicy or acidic foods. Eating small meals and remaining upright after meals may help prevent or ameliorate symptoms. If reflux occurs primarily at night, elevating the head while in bed will also help avoid discomfort. Certain medications, including beta-adrenergic agonists, tranquilizers, sedatives, progesterone, and calcium-channel blockers, may worsen symptoms. The use of antacids is likely to bring short-term relief of intermittent symptoms but may interfere with absorption of other medications. Step-up therapy for more severe symptoms begins with an 8-week course of a proton pump inhibitor, such as omeprazole (Prilosec), esomeprazole (Nexium), or lansoprazole (Prevacid). No specific proton pump inhibitor appears to be more effective than another. A proton pump inhibitor should be taken in the morning, before the first meal of the day. A second dose in the evening may be needed for nighttime symptoms. If only partial relief is achieved, adding a second dose or changing to a different proton pump inhibitor may be effective.[61] A woman whose symptoms are unresolved following an 8-week trial of a proton pump inhibitor should

be referred for consultation with a specialist to assess the need for endoscopy or possible fundoplication of the stomach.[61]

Ulcers

Peptic ulcers are open lesions of the stomach or duodenum, penetrating through the mucosa into muscle. An estimated 15 million people, representing almost 7% of non-institutionalized adults in the United States, have these lesions.[62] Common etiologies include *Helicobactor pylori* infection, a condition responsible for 70% of gastric ulcers and 95% of duodenal ulcers, and excessive use of NSAIDs, such as ibuprofen or aspirin.

Testing for *H. pylori* is indicated in adults with a peptic ulcer, history of peptic ulcers, or undiagnosed dyspepsia. The American College of Gastroenterology does not recommend testing unless treatment is planned. Noninvasive testing methods include antibody screens, urea breath testing, and fecal antigen testing.[63] Endoscopy is warranted in individuals older than 50 years and those with alarming symptoms such as bleeding, unexplained weight loss, change in bowel habits, or recurrent vomiting. Endoscopic testing offers excellent sensitivity and specificity, but is invasive and expensive.[61] Thus, for midwives, the decision to consult or refer for management of suspected *H. pylori* ulceration is made early in the evaluation process.

In addition to medication, counseling about avoiding use of aspirin and NSAIDs, stress reduction, and smoking cessation are all useful interventions for management of persons with ulcers. By themselves, these lifestyle interventions are not curative; instead, antibiotic therapy is necessary to eliminate *H. pylori* from the gastrointestinal tract and is essential for healing. Recommended initial therapies include a proton pump inhibitor and clarithromycin (Biaxin) plus either amoxicillin (Amoxil) or metronidazole (Flagyl) for 10 to 14 days. Common side effects of these regimens include headache, altered taste, diarrhea, and stomach upset, and women should be aware that they will have gastrointestinal symptoms during therapy as a means to decrease nonadherence.[63] The use of probiotics may offer some relief for side effects and assist in maintaining normal gastric flora.[64] Sucralfate (Carafate) is also often used to promote healing and reduce inflammation. Gastric ulcers that remain unresolved need to be evaluated to exclude cancerous lesions of the stomach.

Abdominal Pain

Abdominal pain has many causes, both gynecologic and non-gynecologic. **Table 6-14** lists some of these etiologies. The diversity of differential diagnoses for women with abdominal pain reinforces the idea that midwives confronted with acute abdominal pain should not hesitate to seek consultation when the diagnosis is unclear.

Table 6-14	Common Differential Diagnoses for Abdominal Pain[a]
Aortic dissection Appendicitis Bowel obstruction	

Cholecystitis
Constipation
Cystitis
Diarrhea
Diverticulitis
Ectopic pregnancy
Endometriosis
Gastroenteritis
Hernia
Inflammatory bowel disease
Lower lobe pneumonia
Mittelschmerz
Ovarian torsion
Ovarian cyst
Pancreatitis
Pelvic inflammatory disease
Pyelonephritis
Ulcer

[a] This list is not comprehensive.

When a woman presents with abdominal pain, assessment begins with a comprehensive history. The onset, description, duration, associated symptoms, and precipitating or relieving factors are determined, as well as identifying whether the pain is localized and, if so, to which quadrant.

Acute Abdomen

Acute abdomen refers to sudden severe abdominal pain and is a medical emergency. Characteristics that distinguish the acute abdomen include abdominal rigidity or distension, guarding, rebound pain, tachycardia, and decreased or absent bowel sounds. Fever may be present but is not essential to the diagnosis. Vomiting as well as urinary, bowel, or vaginal symptoms may be present. Immediate referral for prompt physician evaluation is needed.

Gallbladder Disease

Nearly 20% of the population may have asymptomatic gallstones; as many as 33% will become symptomatic in the future and require evaluation or treatment.[65] Cholecystitis is an inflammation of the gallbladder—the organ that collects, concentrates, and dispenses into the digestive tract the bile produced by the liver. When excess cholesterol triggers a crystallization process, gallstones are formed. If gallstones become symptomatic, they usually cause only mild biliary colic or a sharp pain after a fatty or large meal that may last a few hours and resolve. Choledocholithiasis is blockage of the common bile duct by gallstones.[65]

Risk factors for developing gallbladder disease include obesity followed by rapid weight loss, hypertriglyceridemia, female gender, pregnancy, older age, diabetes, and genetic

predisposition. When cholecystitis develops, sharp epigastric pain may last for several hours or days and is often associated with nausea and vomiting. Women with acute attacks present with severe, persistent right upper quadrant pain, often radiating to the right shoulder blade or the central back opposite the epigastrium. Murphy's sign (**Figure 6-2**) is positive if the woman stops inspiration with deep palpation of the right upper quadrant of the abdomen. Leukocytosis, elevated liver function tests, and elevated bilirubin are common laboratory findings. Ultrasound is the most effective diagnostic tool for identifying gallbladder disease.

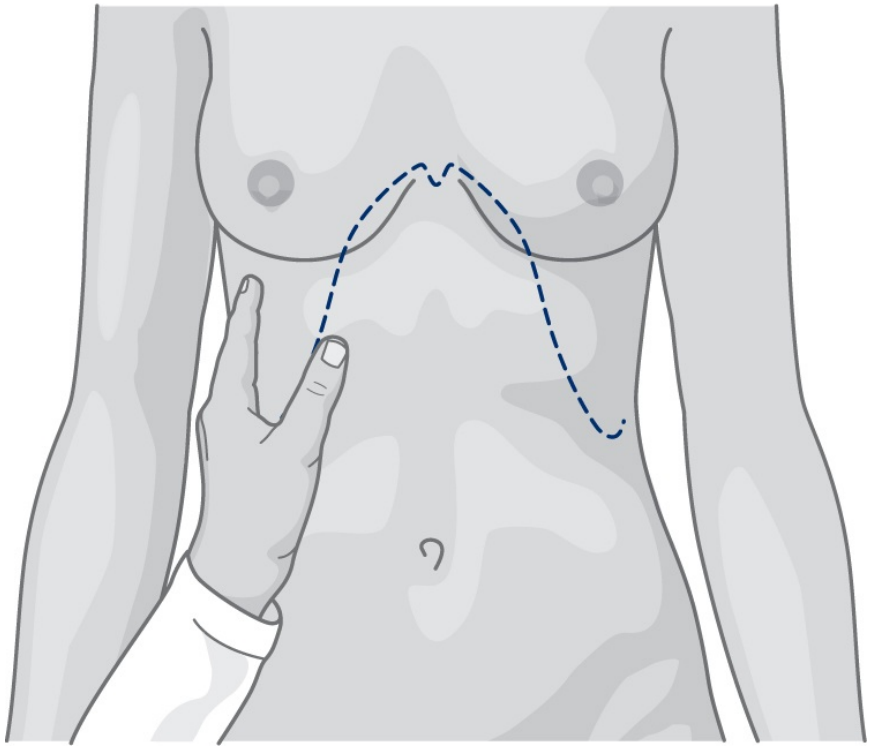

Figure 6-2 Murphy's sign.

Once a diagnosis of cholecystitis is considered, the midwife should refer the woman for physician care. Prompt surgical removal of the gallbladder is the usual treatment.[65] None of the nonsurgical approaches to treatment of gallstones has proved to be an effective alternative to surgery, but rarely nonsurgical options may be considered in individuals who are not good surgical candidates.[65]

Appendicitis

When the appendix becomes obstructed, enlarged, and unable to drain, the subsequent bacterial response leads to appendicitis. After decades of decreases in its incidence, the rate of acute appendicitis is increasing in the United States.[66] Although the most common age at which individuals develop appendicitis remains 10 to 20 years, this diagnosis is becoming more common among individuals older than 40 years.[66] One suggested source of the relative

increases in appendicitis incidence is improved diagnostic accuracy, particularly the accuracy of computed tomography, which decreases missed diagnoses attributed to other, usually gynecologic, pelvic symptoms.[66]

The classic descriptive symptoms for appendicitis are anorexia and generalized abdominal pain, resolving into acute right lower quadrant abdominal pain, vomiting, and fever. A complete blood count will show leukocytosis with an increased neutrophil ratio. Deep tenderness over McBurney's point in the lower right abdomen is an early sign of acute appendicitis. Rebound pain with release of pressure from the left lower abdomen is known as Rovsing's sign. **Figure 6-3** illustrates the locations of McBurney's point and Rovsing's sign.

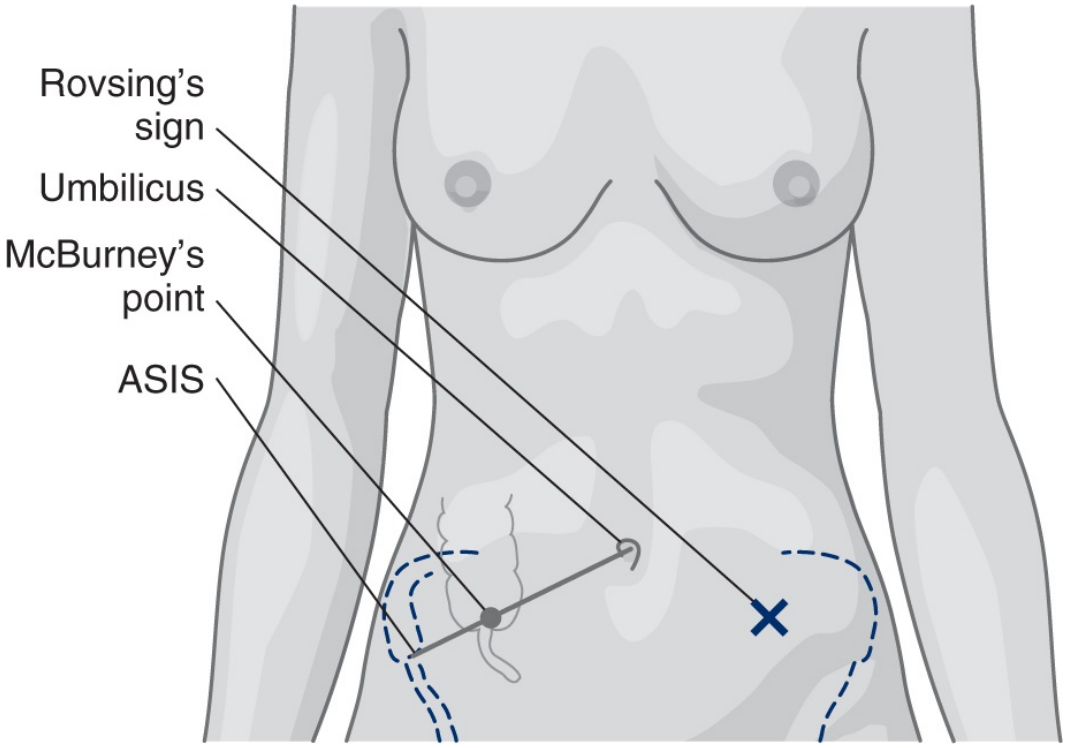

Figure 6-3 McBurney's point and Rovsing's sign. McBurney's point is on the abdominal wall that lies between the umbilicus and ASIS, and is usually two-thirds the distance from the umbilicus toward the ASIS. The most common placement is at the base of the appendix.

Abbreviation: ASIS, anterior superior iliac spine.

When appendicitis is suspected, the woman should be referred immediately for evaluation and possible surgery. Antibiotic therapy for nonsurgical management of appendicitis is being studied, but is not yet a standard practice.[67]

Gastroenteritis and Acute Diarrhea

Some women report diarrhea when they have any change in bowel habits that produces soft, frequent, or less-formed stools. True diarrhea is characterized by increased water content and may include mucus or bloody discharge. Women who report having diarrhea are asked about associated symptoms such as cramping, nausea or vomiting, or fever. Careful examination of

the abdomen, including auscultation of bowel sounds, palpation, and percussion, is necessary.

Acute diarrhea is predominantly infectious; chronic diarrhea, lasting for more than 2 consecutive weeks, can result from a variety of infections, medication use, chronic illness, malabsorption syndromes, stress, and irritable bowel syndrome. Recent travelers, the elderly, members of an identified community outbreak, and those recently prescribed antibiotics require closer attention to a specific diagnosis. Women with chronic watery diarrhea are referred for physician consultation for further testing.

Viral gastroenteritis is a generally self-limiting disease, in which oral exposure to a pathogenic virus such as Norovirus or rotavirus leads to explosive onset of nausea, vomiting, and/or diarrhea, fever, and malaise within 1 to 3 days of exposure. The abdomen is tender; no guarding is present. Bowel sounds are increased. Norovirus alone accounts for 58% of acute foodborne illnesses.[68] Other causes of diarrhea-linked infections include *Escherichia coli* species, *Salmonella*, and a host of other bacteria, most of which are foodborne pathogens.

The majority of cases of diarrhea in healthy adults will spontaneously regress within 1 to 4 days. Rest and oral fluids are the basic components of care. Medications such as diphenoxylate (Lomotil) or loperamide (Imodium) may be offered to decrease the frequency of stools. Intravenous rehydration with electrolytes is indicated for severe dehydration and for individuals at increased risk, such as the elderly and immunocompromised persons.

Investigation of acute diarrhea includes a stool sample to check for white blood cells or frank bleeding. Laboratory evaluation of electrolytes should be reserved for more severe or persistent cases when dehydration is suspected. If symptoms are not resolving or the woman becomes dehydrated, stool samples for culture or for ova and parasites (depending on the suspected pathogen) as well as a toxin assay for *Clostridium difficile* (with recent antimicrobial use) would be indicated.

Traveler's diarrhea (TD), as distinguished from Norovirus infections acquired in large travel groups such as cruises, is more likely to have a bacterial source—specifically, *E. coli* or another enterococcus. Prevention through hand washing and food selection may help reduce the risk of contracting TD, though in high-risk regions the risk can never be completely eliminated. High-risk regions include Asia, the Middle East, Africa, Mexico, and Central and South America.[69] When infection occurs, early rehydration is essential, and antimotility agents such as loperamide may provide symptom relief.[69] When antibiotic treatment does not resolve symptoms, parasitic pathogens should be considered based on the location of travel.

Constipation

Straining to produce hard stools, infrequent bowel movements (fewer than once in 3 days), and painful defecation are characteristic of constipation. Estimates of the frequency of constipation average almost 15% of the female U.S. population, with the elderly having a greater prevalence.[70] Initial questioning of women with these symptoms should include an assessment of their "usual" bowel function. Among healthy women, inadequate dietary fiber, decreased fluid intake, and iron therapy for anemia, whether prescribed or self-initiated, are common causes of constipation. Other medications, such as tricyclic antidepressants (e.g., amitriptyline [Elavil]), anticholinergics (e.g., ipratropium bromide [Atrovent]), and calcium-channel

blockers (e.g., diltiazem [Cardizem] and verapamil [Calan]), may slow peristalsis and increase stool transit time, leading to constipation. Misuse of laxatives leading to decreased natural stimulation of the bowel is also common, particularly among the elderly. Stress, anxiety, and depression may lead to changes in bowel habits, as may a history of sexual abuse. Other serious causes include hypothyroidism, cancer, strictures, and opioid use. A careful history and physical assessment of women with any chronic bowel changes is necessary to rule out serious underlying disease that would require a referral.

Management of chronic constipation in healthy women includes counseling about diet and exercise, as well as increased fluid intake. Avoidance of straining and recognizing the physical cues that indicate the need to defecate are included in teaching. Women should also be counseled to stop the overuse of laxatives, cathartics, and enemas. If any medication is necessary during early treatment, a bulk-forming OTC drug such as Metamucil should be used; however, adding fiber to the diet is a better strategy because a pattern of healthy eating will help maintain normal function. If symptom relief is not obtained with the preceding measures, a trial of laxatives such as docusate sodium (Colace) is in order before referring the woman to a physician.

Irritable Bowel Syndrome Versus Inflammatory Bowel Diseases

Irritable bowel syndrome (IBS) is a functional bowel disorder that consists of lower gastrointestinal tract symptoms of increased bloating, diarrhea, or constipation in the absence of any structural or biochemical cause. This condition is chronic in nature, it tends to wax and wane, and is one of the most common presentations in primary care practice. The current definition (Rome III) includes onset associated with changes in the frequency or composition of the stool and pain relief with defecation, lasting for more than 6 months.[71] To meet the diagnostic criteria, the symptoms need not be continuous. Intermittent symptoms totaling 12 weeks are considered significant.[71] Increased or decreased stool frequency, abnormal stool formation (either hard or watery), bloating, difficulty in the passage of stool (straining, urgency, or failure to completely empty the bowel), and mucus in the stool are further confirmation of the diagnosis. Because the symptoms are unstable, the terms “IBS with diarrhea” and “IBS with constipation” are commonly used.

The onset of IBS usually occurs during the young adult years. Because organic causes of bowel changes are more frequent with increasing age, a new diagnosis should be made with care in adults older than 40 years. Women are more often affected than men and are more likely to have alternating symptoms of diarrhea and constipation. Assessment includes evaluation for bowel obstruction, including malignancies, and for gastrointestinal bleeding. Irritable bowel syndrome should not be confused with inflammatory bowel diseases such as Crohn’s disease and ulcerative colitis, which are chronic, recurrent inflammations of the bowel. Symptom relief after having a bowel movement is strongly suggestive of IBS.

Although the symptoms of IBS are common among adults who do not seek care, those who do are more likely to be distressed by the condition. Thus, an important step in managing care for individuals with this disorder is building a trusting relationship. Education about IBS, reassurance about the course and management possibilities, and dietary modification are

important in helping women manage their symptoms effectively.[72] Some individuals can identify foods that trigger symptoms, but not enough evidence exists to recommend specific dietary changes.[72] Probiotics may relieve bloating and flatulence for some individuals. The American Gastroenterological Association has made conditional recommendations supporting the use of antispasmodic medications, tricyclic antidepressants, and various medications for symptomatic relief of constipation or diarrhea.[72]

Because of the strong likelihood of underlying psychological distress among women with IBS, a careful assessment for anxiety disorders and depression is warranted. Considerations in managing this aspect of the disease include the use of antidepressants, psychotherapy, and supportive behavioral therapy.

In contrast, inflammatory bowel diseases are autoimmune disorders that affect the small and large intestine. Examples include Crohn's disease and ulcerative colitis. Inflammatory bowel diseases often have a genetic component. Inflammatory bowel diseases have symptoms that overlap with those of irritable bowel disorder but some dissimilarity. For example, both disorders are associated with intestinal symptoms but irritable bowel disorder is more likely to be triggered by dietary factors whereas inflammatory bowel disease is more unpredictable. Persons with inflammatory bowel diseases need physician care and often require medications that can be complex to manage.

Hepatitis

Hepatitis is the generic term used to describe inflammation of the liver, regardless of etiology. The most common causes of hepatitis include the infections caused by pathogenic viruses identified by the letters A through E and linked to liver disease by the acute and chronic nature of the conditions. While hepatitis A and E are spread by the fecal–oral route, hepatitis B, C, and D are spread by contact with blood and body fluids and can be contracted sexually. Hepatitis A and B are the most common forms of hepatitis in the United States. Although there are fewer new cases per year of hepatitis C than hepatitis A and B, infection with the C variant becomes chronic in approximately 75% to 85% of persons who are infected with it. In contrast, hepatitis B develops as a chronic state in fewer than 6% of adult cases.[73] Together, the A, B, and C strains are responsible for most new viral hepatitis diagnoses in the United States.[73]

Hepatitis D occurs as a coinfection with hepatitis B or as a secondary infection, and requires the presence of hepatitis B for its transmission. Hepatitis D is uncommon in the general population of North America, although it may occur in intravenous drug users and persons with frequent exposure to blood products (e.g., persons with hemophilia) as well as their sexual contacts.[74]

Hepatitis E is an enterically transmitted virus, often associated with contaminated water sources; it is most commonly found in Asia, the Middle East, South America, and Latin America. Hepatitis E has been diagnosed in the United States primarily in individuals traveling from low-resource countries, although it can be associated with foodborne transmission. This disease is frequently associated with only mild symptoms, and does not result in a carrier state.[74]

Hepatitis can also result from generalized infection by other viruses, including cytomegalovirus, Epstein-Barr virus, herpes simplex virus, and measles virus. Nonviral causes of liver inflammation include autoimmune disease, bacterial sepsis, and syphilis. Hepatitis can also be chemically induced by chronic alcohol ingestion or by medications such as acetylsalicylic acid (aspirin), acetaminophen (Tylenol), phenytoin (Dilantin), isoniazid (Niazid), and rifampin (Rifadin).

Symptoms common to all types of hepatitis include jaundice, dark-colored urine, abdominal pain, clay-colored stools, fatigue, loss of appetite, and nausea or vomiting. Laboratory abnormalities include elevated liver function tests. Testing for antibodies to the various viral causes of hepatitis, followed by consultation or referral for management, is appropriate.

Hepatitis A

Hepatitis A virus (HAV) is an RNA virus transmitted through the fecal–oral route. Most cases of hepatitis A arise during community-wide outbreaks. In the United States, vaccination has been successful in limiting the rate of infection, although it still occurs occasionally. In adults, most cases are symptomatic.[75] Contaminated water and food (especially shellfish) are typical sources of infection, with most cases being associated with close personal contact with an infected person, although blood-borne transmission has been documented in both infants and

adults.[74]

Hepatitis A has an incubation period of 28 days (range: 15–50 days), with the virus being shed through the feces approximately 2 weeks prior to the emergence of clinical symptoms. The infection has a short acute phase of 10 to 15 days, with symptoms resolving within 2 months, although as many as 15% of symptomatic persons have prolonged or relapsing disease lasting up to 6 months.[74] This self-limited disease does not result in chronic infection and is managed with symptomatic treatment and monitoring for worsening liver disease.[74]

Serologic testing with a finding of immunoglobulin M (IgM) antibody is required to confirm infection. IgM anti-HAV usually becomes detectable 5 to 10 days before the onset of symptoms and can persist for up to 6 months after infection. Immunoglobulin G (IgG) anti-HAV appears early in the course of the disease and indicates lifelong protection against the disease.[76]

Since 1995, two licensed inactivated hepatitis A vaccines have been available in the United States. Recommendations for hepatitis A immunization are described in detail in the *Health Promotion Across the Lifespan* chapter.

Hepatitis C

Hepatitis C virus (HCV) is rarely identified at the time of exposure. The CDC estimated that more than 30,000 cases occurred in the United States in 2014, but only 2194 cases were reported.[75] Of the more than 3 million persons currently living with chronic hepatitis C, the majority were probably exposed during the 1970s and 1980s, when rates of this infection reached their highest point. Risk factors include birth between 1945 and 1965, ever use of injectable or intranasal drugs, long-term hemodialysis, known exposure (healthcare worker, organ or blood recipient from a positive donor), HIV infection, and abnormal liver enzyme test results. Healthcare workers in general, long-term partners of individuals who are hepatitis C positive, and those with a history of multiple partners or sexually transmitted diseases may be tested for HCV infection, although the utility of screening these individuals in unclear.[77,78]

Transfusion with unscreened blood is an uncommon risk today for contracting hepatitis C. In contrast, unsterile tattoos from unlicensed providers, whether in social settings or during incarceration, have been linked to an increased risk of hepatitis C.[79] All-cause mortality is increased by infection with hepatitis C; racial disparities in rates of infection and mortality from hepatitis C exist as indicated by higher rates among Mexican Americans, Hispanic Americans, and blacks compared to whites.[80]

The period of incubation for hepatitis C ranges from 2 weeks to 6 months. Approximately 30% of individuals newly infected with HCV are symptomatic.[75,77] Chronic disease develops slowly, and both excessive alcohol use and obesity have been associated with progression.

Targeted screening for the hepatitis C virus is based on risk factors and is described in detail in the *Health Promotion Across the Lifespan* chapter. Diagnosis of hepatitis C infection is made by serum enzyme immunoassay (EIA) or chemiluminescent immunoassay (CLIA) detection of antibody to the virus. Hepatitis C antibody testing is accurate 4 weeks to 6 months after exposure. If the test for antibody to hepatitis C is positive, qualitative and quantitative HCV-RNA polymerase chain reaction (PCR) testing should be performed. Because of the high

(70% to 85%) incidence of chronic disease, serum alanine aminotransferase (ALT) and quantification of HCV-RNA (viral load) should be performed.[77,80]

Currently, there is no vaccine that can prevent infection with hepatitis C although identification of treatments including curative therapies is rapidly evoloving.[78] Counseling, including use of barriers with sexual activity and avoiding sharing intravenous drug paraphernalia, is essential. Treatment for acute and chronic hepatitis C should be managed by a physician familiar with the currently available therapeutic regimens.

Conditions of the Genitourinary System

The close proximity of the urinary tract to the reproductive organs means that women frequently call a midwife for management of urinary tract symptoms. Outpatient evaluation and management of uncomplicated cystitis is an essential skill for midwives, as are prompt recognition and triage of more serious conditions. Definitions and diagnostic criteria for urinary tract infections are listed in **Table 6-15**.[81,82]

Table 6-15	Definitions and Diagnosis of Urinary Tract Infections
Asymptomatic bacteriuria	Urine culture demonstrating ≥ 10^5 colonies of no more than 2 different microorganisms from appropriately collected clean catch midstream urine specimen culture in a woman without fever (≤ 38°C), urgency, frequency, dysuria, or suprapubic tenderness and with no history of indwelling catheter use within prior 7 days
Cystitis	Infection limited to the lower urinary tract, typically with symptoms of dysuria, frequency, and urgency
Pyelonephritis	Infection ascending to renal system, accompanied by fever, flank pain with or without lower urinary tract symptoms but with bacteriuria
Uncomplicated UTI	Cystitis or pyelonephritis occurring in a woman with normal genitourinary tract and no complicating factors
Complicated UTI	Cystitis or pyelonephritis occurring in a woman with recurrent UTIs, functional or structural abnormalities, an indwelling catheter, or associated systemic comorbidities such as metabolic disorders
Recurrent UTI	Recurrence involves ≥ 2 UTIs within 1 year *Relapse or persistent infection* occurs when the infective organism is identical to the pretreatment organism and is typically related to persistence within the genitourinary tract and occurring within 2 weeks of completion of the original treatment *Reinfection i*mplied infection with a new organism after adequate treatment but can include a new bacterial strain or a previously isolated strain that has persisted in the colonizing flora of the gut or vagina; typically a reinfection occurs > 2 weeks after the original treatment or following a negative test of cure
Diagnostic criteria for acute UTI	In a woman with a normal urinary tract and no other recognized cause for signs and symptoms, and no urinary catheter in place within the previous 48 hours, the diagnosis of UTI is confirmed by the presence of urgency, frequency, dysuria, suprapubic tenderness, costovertebral angle pain or tenderness, or fever (> 38°C) if ≤ 65 years of age AND 1. A positive urine culture of ≥ 10^5 CFU/mL with no more than 2 species of microorganisms OR 2. A positive urine culture of ≥ 10^3 CFU/mL with no more than 2 species of microorganisms with urinalysis demonstrating: a. positive dipstick for leucocyte esterase and/or nitrite b. pyuria (urine specimen with ≥10 WBC/mm^3 or ≥ 3 WBC/high power field of unspun urine c. microorganisms seen on Gram stain of unspun urine

Abbreviations: CFU, colony-forming units; UTI, urinary tract infection; WBC, white blood cell.

Reproduced with permission from O'Dell KK. Pharmacologic management of asymptomatic bacteriuria and urinary tract infections in women. *J Midwifery Womens Health.* 2011;56:248-265.[82] © 2011, with permission from Wiley.

Acute Cystitis

Uncomplicated acute cystitis is defined variously as the presence of 1000 or more colony-forming units (CFU) per milliliter of urine in a culture from a catheter specimen for symptomatic women or, more traditionally, as 100,000 or more CFU per milliliter whether or not symptoms of a lower urinary tract infection (UTI) are present. However, lower CFU counts may be associated with infection and in a woman with symptoms, a CFU of less than 100,000 CFU per milliliter should be interpreted with caution.

"Asymptomatic bacteriuria" is the term applied when symptoms are absent and 100,000 CFU per milliliter or more of a single organism grow in a urine culture. The predominant organism implicated in uncomplicated lower urinary tract infection is *E. coli*, with *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterobacter*, and *Enterococcus* species making up the majority of the other pathogens that are associated with UTI.[81-83]

Lower urinary tract infections are among the most common infections that women experience. Once a woman has such an infection, she is at risk for recurrence, often within a few months. Risk factors for UTI include sexual activity, barrier contraceptive and/or spermicide use, vaginal infections, trauma/or manipulation, increasing age, and genetic susceptibility.[84] Symptoms of a lower UTI include pain on urination, increased voiding frequency, and persistent suprapubic or low back pain. Because the symptoms of UTI overlap with those of sexually transmitted infections such as chlamydia, sexually active young women should be screened as indicated[84] and described in the *Health Promotion Across the Lifespan* chapter.

Lower UTI is frequently diagnosed based on symptoms and urinalysis findings consistent with bacteriuria and pyuria, in the absence of vaginal pain or discharge.[85] When cystitis is suspected, a culture and sensitivity should be obtained while the woman is symptomatic to confirm that a UTI is the cause of symptoms and to ensure that an antibiotic is prescribed to which the pathogen is sensitive. Between 30% and 50% of women with one UTI will have a recurrence within 1 year.[84]

Recurrent lower UTI is diagnosed when the woman has three or more infections proven by culture within a year. Identifying characteristics of uncomplicated recurrences include frequent sexual activity, a prior history of pyelonephritis, and rapid symptom resolution after treatment. Nocturia, hematuria, dyspareunia, and persistent symptoms after antibiotic therapy are indicative of another source of irritation, such as interstitial cystitis.[86] Among postmenopausal women, recurrent lower UTI is associated with urinary incontinence, cystocele, and prolapse. The use of vaginal estrogen creams or rings help prevent recurrent lower UTI in this population by restoring integrity to the vaginal and urethral tissues affected by estrogen deprivation.[86]

Recommendations for treatment of women with lower UTI have become more complicated as resistance to various antibiotics has emerged.[82] For low-risk women, judicious use of hydration, frequent voiding, anti-inflammatory analgesics, and probiotics with Lactobacilleae may become the first-line therapy, to be supplemented with antibiotics if symptoms persist for three days.[87] Nitrofurantoin (Macrodantin) or the combination of nitrofurantoin monohydrate

with macrocrystals (Macrobid) is preferred if there is no suspicion of pyelonephritis, or TMP-SMX (Bactrim) if that regimen has not been used within 3 months. Amoxicillin or ampicillin should never be used as a sole agent; fluoroquinolones, amoxicillin–clavulanate (Augmentin), and beta-lactams should be reserved for more serious infections whenever possible or if the recommended drugs are contraindicated.[82]

Despite popular belief, cranberry products are not useful in resolving UTIs and may exacerbate symptoms given the acidity of cranberry is irritating to the bladder. Cranberry is not recommended for treatment of a UTI. Studies of use of cranberry products for prevention of UTIs have had conflicting findings and most of the studies conducted to date had methodologic problems that limit generalizing their findings.[88] Although there is little harm in the use of these products, cranberry should not be recommended as an effective prevention strategy at this time.

Interstitial Cystitis

Interstitial cystitis is a persistent inflammatory bladder condition that is associated with suprapubic or retropubic pain, dysuria, frequency and urgency, dyspareunia, and nocturia. The term "painful bladder system" is used as an alternative when symptoms do not meet all criteria for diagnosis but no other cause of inflammation and pain can be identified. Over time, the bladder wall can become irritated or scarred, leading to the development of submucosal bleeding. Diagnosis is often delayed because the symptoms are mistaken for lower urinary tract infection. No evidence can be found for a microbial pathogen; however, some women report an acute UTI prior to the onset of symptoms. Numerous potential contributors to causation have been proposed, and links to other chronic pain syndromes are recognized.[89] More than 3 million adult women are estimated to have pain and urinary symptoms of interstitial cystitis/painful bladder syndrome in the United States.[90]

Midwives can offer women with interstitial cystitis/painful bladder syndrome counseling on restricting alcohol and possible food triggers such as spicy or high-acid foods, caffeine, and chocolate; tobacco cessation; and bladder training. Referral for further evaluation, including a possible biopsy to rule out bladder cancer, and medication is often warranted.[90]

Pyelonephritis

Women with abdominal pain should be evaluated for acute pyelonephritis, an inflammation of the kidneys. The characteristic presentation of pyelonephritis is severe flank pain and fever with associated chills, nausea or vomiting, and painful urination. Assessment of costovertebral angle tenderness (CVAT) by striking beneath the 12th rib in the acute angle formed with the spine can help to assess the location of the pain (**Figure 6-4**). The risk factors and pathogens associated with pyelonephritis are the same as those for lower UTI. The diagnosis should be confirmed by a urinalysis, which will be positive for white blood cells or the presence of pyuria, and by urine culture. Additional laboratory tests include blood urea, creatinine, and CBC; an elevated leukocyte count is an indicator of severity.[84]

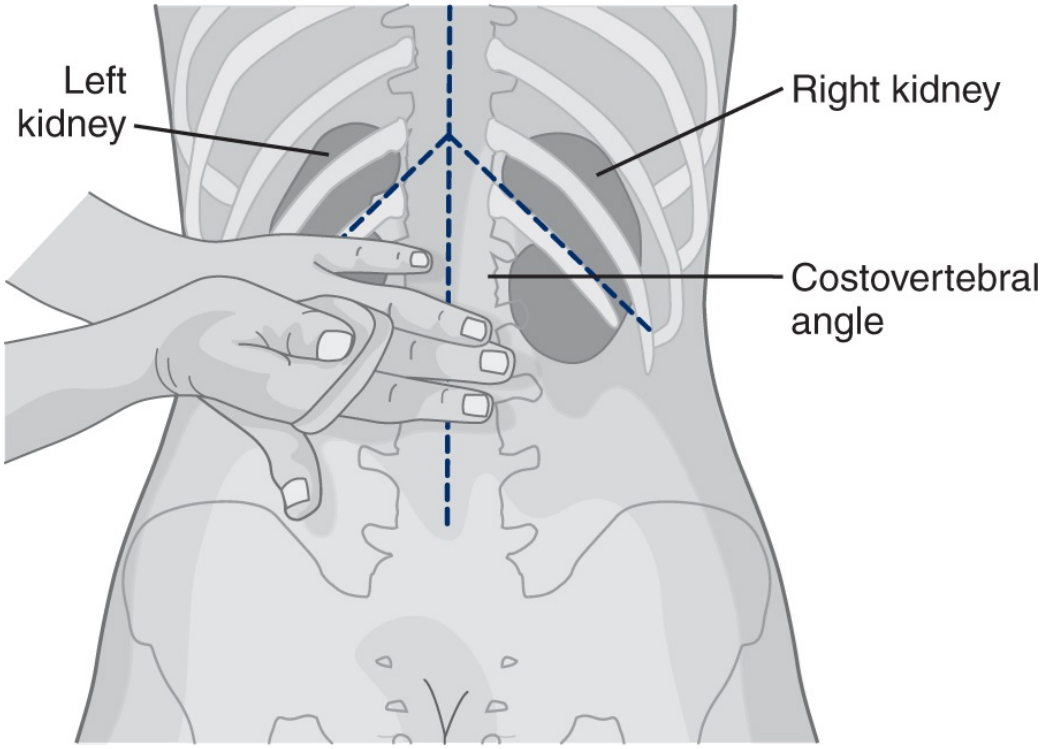

Figure 6-4 Assessing for costovertebral angle tenderness.

Note: Choose the technique that is most comfortable for both examiner and patient.

1. With the woman seated on the examination table, place the palm of one hand over her costovertebral angle on one side of the patient's back. Make a fist out of your other hand. Use the ulnar surface of your fist for striking. Strike the back of the hand that is over the costovertebral angle with the fist of your other hand.

OR

2. Put your hands around the woman's waist and locate by the palpation the costovertebral angles with the flat part of your index and middle fingers on each hand. Alternately strike each costovertebral angle with your fingers by a sudden, upward motion of your hand.

Indications for physician consultation or referral include evidence of severe upper urinary tract infection, frequent recurrence of a UTI, infection with resistant organisms or in women with multiple antibiotic allergies, comorbidities that may affect immune status, comorbidities that may affect the structure or function of the urinary tract, hematuria that persists after treatment, or observed anatomic abnormality.[82] Physician consultation is required when pyelonephritis is suspected; a pending urine culture should not delay consultation. Treatment varies depending on whether it is delivered on an inpatient basis or at an outpatient site. Commonly prescribed drugs include various combinations of ciprofloxacin (Cipro), cephalosporins, fluoroquinolones, aminoglycosides, and penicillins.[82]

Kidney Stones

The usual symptoms of nephrolithiasis (kidney stones) include severe renal colic caused by the

stone passing into the ureter. As the stone enters the bladder, it triggers symptoms resembling those of a urinary tract infection. Hematuria is common but not required for diagnosis. Helical computed tomography without contrast is the preferred confirmatory test.

When kidney stones are suspected, the midwife will need to refer the woman to a specialist for management. While arranging transfer, NSAIDs can be initiated for pain management and are as effective as opioids for this purpose. Small stones, less than 0.5 to 1 centimeter in diameter, can be allowed to pass without surgery, using effective pain management and increasing fluids.[91-93] Calcium-channel blockers and alpha-adrenergic agonists have been used to speed the passage of stones through the ureter, and are associated with decreased pain.[92] Surgical management of kidney stones that are large, obstructive, or associated with infection now relies on extracorporeal shock-wave lithotripsy, ureteroscopy, and percutaneous nephrolithotomy as means to avoid open procedures.

Women have a 7% lifetime risk of developing kidney stones.[94] Recurrence is common, and has been estimated to be as high as 50% within 5 years.[94]

Endocrine Conditions

Metabolic Syndrome

Obesity, especially central obesity, is associated with an increased risk of insulin resistance and elevated blood cholesterol. The National Cholesterol Education Program has defined metabolic syndrome as atherogenic dyslipidemia, elevated blood pressure, dysglycemia, a prothrombotic state, and a pro-inflammatory state.[30] **Table 6-16** provides one commonly accepted definition of metabolic syndrome in women.[95]

Table 6-16 **National Cholesterol Education Program Diagnostic Criteria for Metabolic Syndrome**

Positive diagnosis with any three of the following:
Waist circumference ≥ 88 cm in women
Serum triglycerides ≥ 150 mg/dL or treatment to reduce triglyceride levels
Serum HDL-C < 50 mg/dL or treatment for reduced HDL-C
Blood pressure ≥ 130/85 mm Hg or treatment for hypertension
Fasting plasma glucose ≥ 110 mg/dL or treatment for hyperglycemia

Abbreviation: HDL-C, high-density lipoprotein cholesterol.

Based on National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) final report. *Circulation*. 2002 Dec 17;106(25):3143-3421.[95]

Women with one or more of these characteristics should be assessed with blood pressure measurement, waist circumference measurement, fasting glucose, and a full cholesterol panel. Counseling about lifestyle changes, including weight loss, increased exercise, and dietary changes, is essential. Women should be referred as appropriate for evaluation and pharmacologic treatment and/or management of hyperlipidemia, hypertension, or diabetes.

Diabetes Mellitus

The definition of diabetes mellitus is based on the underlying cause of hyperglycemia. “Prediabetes” is the term used to describe women with abnormal blood glucose values that do not meet the measurement that defines diabetes. **Table 6-17** distinguishes between four types of diabetes.[96] In addition to the four classifications listed in **Table 6-17**, a fifth term, pre-diabetes, is used to identify persons with abnormal plasma glucose values that do not reach criteria for diabetes. These individuals are at increased risk for developing diabetes and should be monitored closely.

Table 6-17 **Classification of Diabetes**

Classification	Description
Gestational	Diabetes diagnosed in the second or third trimester of pregnancy that is not clearly overt or

diabetes	preexisting to the pregnancy (type 1 or type 2) diabetes.
Type 1 diabetes	Diabetes resulting from beta-cell destruction, usually leading to absolute insulin deficiency
Type 2 diabetes	Diabetes resulting from progressive loss of pancreatic beta-cell insulin secretion in the face of increased insulin resistance
Other types of diabetes	Diabetes due to other causes such as cystic fibrosis, pancreatic disease, drug-induced or chemically induced

Based on American Diabetes Association. Standards of medical care in diabetes—2017. *Diab Care.* 2017;40(suppl 1):S1-S135.[96]

Type 1 diabetes is almost universally mediated by the immune system and causes pancreatic B-cell destruction. It is most commonly diagnosed in children or young adults (hence the older name of "juvenile" diabetes) and accounts for approximately 5% to 10% of all cases of diabetes.[96] *Type 2 diabetes*, which is the most common form of diabetes, is the result of resistance to insulin and the inability of the pancreas to increase insulin production to compensate for this resistance.

Together, diabetes types 1 and 2 affect more than 29 million persons in the United States, of whom approximately 8 million (27.8%) remain undiagnosed; 13.4 million of the people with diabetes are women.[97] Rates of diabetes increase as persons age, and in persons with obesity. A first-degree family member with diabetes, lack of physical activity, and smoking are other factors that increase risk.[96,98] A diet high in red meat, high-fat dairy, and processed carbohydrates and sweets increases the risk for developing diabetes regardless of other risk factors.[97] Ethnic groups with an increased risk of developing diabetes include non-Hispanic blacks, Mexican Americans and Puerto Ricans, Southwest American Indians, and Asian Americans. Although having a large-for-gestational-age infant is no longer considered a risk factor for diabetes, women with a history of gestational diabetes and/or polycystic ovary syndrome have demonstrated increased risk.[96]

Screening for diabetes mellitus should be performed for all women older than 45 years, and for anyone with a BMI of 25 kg/m^2 or greater (BMI $\geq$ 23 kg/m^2 among Asian Americans) and one or more risk factors for cardiac disease.[96] Screening tests include glycosylated hemoglobin A1c (HbA1c), fasting blood glucose, and the 2-hour glucose tolerance test.[96] HbA1c measures the average plasma glucose level over the last month; its results are expressed as the percentage of total hemoglobin. This test can be used to assess either the degree of elevated blood glucose over time in persons with a new diagnosis of diabetes or the degree of glycemic control in persons who are being treated for diabetes. Type 2 diabetes is diagnosed if the HbA1c result is equal to or greater than 6.5%.

Table 6-18 summarizes the criteria for the diagnosis of diabetes.[96,97] Any one of the three tests can be used but the diagnosis is not made until the same test is repeated twice. The repeat test requires a new blood sample and can be performed right away. Women newly diagnosed with diabetes should be referred to a healthcare provider skilled in treating women with diabetes.

Table 6-18 **Diagnosis of Diabetes Mellitus**

Test	Description	Glycemic Goals Following Treatment
Any one of the following three tests will confer the diagnosis of diabetes if repeated twice:		
Hemoglobin A1c[a] ≥ 6.5% or	Fasting not required.	< 7.0%
Fasting plasma glucose ≥ 126 mg/dL or	Fasting is defined as no caloric intake for at least 8 hours.	80–130 mg/dL
2-hour plasma glucose ≥ 200 mg/dL after a 75-g glucose load	This test will diagnose more individuals with diabetes than will hemoglobin A1c or a fasting plasma glucose level.	< 180 mg/dL 2-hour postmeal

Abbreviation: RBC, red blood cell.

[a] Hemoglobin A1c measures the percentage of glycosylated hemoglobin present, Glycosylated hemoglobin is hemoglobin that is coated in glucose. As plasma glucose levels rise, the amount of glycosylated hemoglobin increases. Glucose stays attached to an RBC for the life of the RBC and is therefore an average measure of plasma glucose levels for the prior 3 months.

Based on American Diabetes Association. Standards of medical care in diabetes—2017. *Diab Care.* 2017;40(suppl 1):S1-S135[96]; Inzucchi SE, Majumdar SK. Current therapies for the medical management of diabetes. *Obstet Gynecol.* 2016;127:780-794.[97]

Midwives can plan an important role in some components of care for women with diabetes including diet education, promotion of moderate exercise, counseling for weight loss, and smoking cessation. Women with diabetes need regular gynecologic care and family planning, and may have an increased risk for developing vaginal infections with candidiasis if glucose control is not optimal. All women with diabetes who desire a pregnancy should be encouraged to achieve glucose control prior to becoming pregnant.Hyperglycemia in early pregnancy is associated with miscarriage and congenital anomalies. Preconception counseling and care can have an important positive effect on pregnancy outcomes. Counseling guidelines for women with diabetes who are planning a pregnancy can be found in the *Health Promotion Across the Lifespan* chapter.

The American Diabetes Association recommends beginning lifestyle changes with the addition of the pharmaceutical agent metformin (Glucophage) as soon as type 2 diabetes is diagnosed.[96] Tight glucose control can reduce the incidence of microvascular complications and glycemic targets are based on long-term clinical studies that have identified plasma glucose levels associated with minimal progression of disease. However, this is a progressive disease and frequently second or third medications are added over time to help maintain euglycemia. Multiple new therapies have been developed in the last several years so that treatment can be individualized to minimize side effects and maximize glucose control. Most medication for diabetes work by improving insulin secretion or insulin sensitivity. Others suppress appetite or promote weight loss. Insulin therapy may also be recommended. If a midwife is participating in primary care services for a woman using medication to control diabetes, additional knowledge about the medications and their effects is needed because these medications have wide ranging physiologic effects.[97] The Resources section at the end of this chapter lists websites that have additional education and training about management of diabetes.

Thyroid Disease

Thyroid conditions are common among women of childbearing age, with an overall incidence of more than 5%.[99] These conditions are more common in women compared to men, and more common as age increases. To date, the U.S. Preventive Services Task Force has not made a recommendation for or against screening asymptomatic, nonpregnant adults for thyroid conditions.[100] Other experts recommend screening in adults, with the age of first testing ranging from 35 to 60 years.[101]

Thyroid-releasing hormones from the hypothalamus stimulate pituitary release of thyroid-stimulating hormone (TSH). In turn, TSH stimulates the production and release of triiodothyronine (T3) and thyroxine (T4) from the thyroid gland. Although T3 is the more active form of the thyroid hormones, little is produced in the thyroid itself. Instead, most T3 is produced from circulating T4 as it loses iodine.

When screening for or diagnosing thyroid disease, the first tests performed usually are measurements of TSH and free T4. Among the antibody tests, confirmation of thyroid peroxidase antibodies is associated with chronic autoimmune thyroiditis (Hashimoto's thyroiditis), the predominant cause of overt hypothyroidism. **Table 6-19** identifies the changes in screening laboratory values associated with common thyroid disorders.

Table 6-19 Thyroid Hormone Values in Thyroid Disorders

Condition	Thyroid-Stimulating Hormone	Free T_4	Serum T_3
Graves' disease (hyperthyroid)	Absent	Elevated	Elevated
Subclinical hyperthyroid	< 0.1 mU/L	Normal	Normal
Hypothyroid	High with primary hypothyroidism Low with secondary hypothyroidism	Low	Low/normal
Subclinical hypothyroid	Mildly elevated (< 10.0 mU/L)	Low/normal	

Hypothyroidism

Hypothyroid conditions result primarily from failure of the gland to produce adequate hormone and are more common than hyperthyroidism. The most common cause of hypothyroidism in the United States is the autoimmune disorder known as Hashimoto's thyroiditis. Other causes include treatment of women with Graves' disease, thyroidectomy, and medications. Secondary hypothyroidism, caused by pituitary or hypothalamic disorders, is uncommon. In primary hypothyroid states, the TSH level will be elevated; the pituitary gland secretes excess TSH in response to low levels of T3 and T4.

Uncomplicated primary hypothyroidism usually is treated with thyroid hormone supplementation. Management of hypothyroidism is complex; medication dosage is based on laboratory values and symptom relief. The midwife plays an important role in screening women who present with symptoms of hypothyroidism. When thyroid disease is suspected or confirmed with laboratory values, women should be referred to a healthcare provider

specialized in the treatment of thyroid disease.

Hyperthyroidism

The single most common cause of a hyperthyroid state (also referred to as thyrotoxicosis) is Graves' disease, an autoimmune disease that has a higher incidence among women than men and is the cause of more than 10% of all cases of thyrotoxicosis in young adults. The thyroid is typically enlarged and tender in hyperthyroidism. Many women will notice irritation of the conjunctiva, diplopia, or blurred vision, or present with proptosis (bulging of the eye or displacement forward of the eye in its orbit) and periorbital edema. **Table 6-20** lists the common signs and symptoms of thyroid disease.

Table 6-20 Common Clinical Features of Thyroid Disease

Hypothyroidism	Hyperthyroidism
Bradycardia	Anxiety, nervousness
Cold intolerance	Diarrhea
Constipation	Fatigue
Delay in deep tendon reflex relaxation	Goiter
Depression	Increased sweating
Decreased sweating	Heat intolerance
Dry skin, brittle nails, thinning hair	Hyperreflexia
Edema (nonpitting)	Irregular menses
Fatigue, sleepiness	Increased appetite with weight loss
Goiter	Lid lag, stare
Headaches	Ophthalmopathy
Hoarseness	Palpitations with angina
Lethargy	Tremor
Loss of appetite	Warm, moist skin
Muscle weakness	Weakness
Muscle cramping or pain	
Menorrhagia, amenorrhea (late)	
Pallor	
Slowed speech and body movements	
Weight gain (occasionally loss)	

Other causes of hyperthyroidism include toxic multinodular goiter, toxic adenomas, early stages of Hashimoto's thyroiditis, and postpartum thyroiditis. This disease has also been associated with very high levels of circulating human chorionic gonadotropin (hCG), such as those found in women who have a hydatidiform mole. Subclinical hyperthyroidism is most commonly associated with suppressive thyroid therapy, although mild Graves' disease is a possible cause.

The midwife should refer for physician consultation any woman in whom hyperthyroidism is diagnosed or suspected. Women who are being treated for thyroid disease will need frequent

laboratory assessment of circulating thyroid hormone levels.

Neurologic Conditions

Headaches

Headaches have many causes and differing degrees of risk, and often are divided into two types: primary and secondary. Primary headaches include tension headaches, migraine, and cluster headaches, whereas secondary headaches are rarer and are related to underlying disease such as a neoplasm. A complete health history should be collected for women with headaches, including a clear description of symptoms associated with onset and duration of headaches, frequency of severe headache, frequency of mild headache, level of interference with normal activities, and frequency of medication use to relieve symptoms. Additional questions can be asked about nausea, light sensitivity, and noise sensitivity, all of which suggest a migraine headache. A headache diary can be of help in diagnosis and treatment.[102]

Conditions that can provoke headache as a symptom, such as sinus infection or concussion, are not discussed here, nor are vascular emergencies such as aneurysm and arteriovenous (AV) malformation. Warning signs identified during the history taking and physical examination that require emergency attention are summarized in **Table 6-21**.

Table 6-21	Warning Signs of Headache Emergencies
Rapid onset of severe symptoms	
Alteration in consciousness or mental status	
High fever	
Severe vomiting, especially without nausea	
Neck stiffness	
Neurologic symptoms:	
Weakness	
Loss of balance	
Numbness	
Paralysis	
Vision changes	
Pattern of worsening headache	
Increasing medication use to control headache	
Direct association with exercise or position change	

Tension Headache

According to the International Headache Society (IHS), tension headaches are characterized by bilateral pain, with a pressing or tightening quality and mild to moderate intensity.[103] Such headaches are relatively common, with prevalence rates ranging from 30% to 78%. Sensitivity to light or sound may be present. While the duration of tension headaches may vary from minutes to multiple days, normal physical activity does not affect the sensation. Other than in the most severe cases, nausea does not occur.[103]

Tension-type headaches are classified based on their frequency: infrequent episodic (less than 1 day/month), frequent episodic (1–14 days/month), and chronic.[103] Most individuals with infrequent or moderate-frequency tension headaches do not seek treatment. Among persons with chronic tension headaches, it has been reported that most are able to continue working and managing daily activities, but they are more likely to have mood or anxiety disorders, decreased ability to function, disturbed sleep, and decreased emotional well-being.[104]

Caring for women with episodic tension headaches includes respecting the woman's report of symptoms, assessing for the presence of anxiety or depression, and promoting lifestyle changes that include relaxation and stress reduction. NSAIDs or acetaminophen can be used as initial therapy to relieve symptoms, especially with episodic tension headaches. Combination medications that include caffeine with aspirin (e.g., Excedrin), ibuprofen (Advil), or acetaminophen (Tylenol) are useful when a single medication is not adequate.[105] Both acupuncture[106] and cognitive-behavioral therapy[107] have shown promise in treating tension-type headaches. Prophylactic treatment is not effective or useful in managing episodic headache.[108]

Chronic tension headache is a more severe condition that often requires prophylactic medication. The tricyclic antidepressants—most commonly, amitriptyline—can be used for this purpose; biofeedback, stress reduction, and other nonpharmacologic interventions to interrupt the cycle of headaches can be used as additional modalities.[109,110] When women report chronic headache over several months while using pain relievers, a medication overuse headache should be suspected, and a plan to stop or taper the drugs in question should be implemented. Women with chronic headache should be referred to a neurologist for management.

Migraine Headache

Migraine headache is both common and frequently underdiagnosed in primary care settings, with an estimated 25% of cases being missed. This tendency suggests that a woman with episodic headaches should be assumed to have migraines unless otherwise diagnosed.[111] The prevalence of migraine among women is estimated to be more than 20%.[112] Among all races, women are more likely than men to be diagnosed with migraine; the condition is more common among Caucasians. Incidence of new-onset migraine in women is highest in the decade after menarche, with the median age at new onset being 25 years.[113] Prevalence rises through the fourth decade of life, but then declines thereafter. Migraine is relatively rare among postmenopausal women, and new-onset headaches in this age group should be evaluated carefully for other causes.

Both genetic predisposition and environmental triggers appear to be involved in the development of migraine headache. The underlying cause is an abnormally increased sensitization to neuronal stimuli, beginning in the cerebral cortex and affecting the trigeminovascular system.

The diagnosis of migraine is subdivided based on the presence or absence of an aura, complications, and associated conditions. The International Headache Society defines *migraine without aura* as a "recurrent headache disorder manifesting in attacks lasting 4–72

hours."[103] Typical characteristics of such headaches are unilateral location, pulsating quality, moderate or severe intensity, aggravation by routine physical activity, and association with nausea and/or photophobia and phonophobia.[103] Migraine without aura in women of childbearing age is often related to the menstrual cycle. *Migraine with aura* is characterized by "recurrent attacks, lasting minutes, of unilateral fully reversible visual, sensory or other central nervous system symptoms that usually develop gradually and are usually followed by headache and associated migraine symptoms."[103] Visual, sensory, and speech symptoms associated with aura are reversible.

Migraine is an intermittently recurring event, with well-defined stages: (1) the premonitory stage; (2) aura (if present); (3) headache; and (4) postdrome (**Table 6-22**).[114] The premonitory stage is noted in approximately 30% of those individuals with the condition and occurs up to 48 hours before onset of the actual headache; tiredness, fatigue, malaise, mood changes, and stomach upset are the most common symptoms.[114] Following the headache, variable symptoms may persist for hours or days. Over time, migraine may progress from an episodic to a persistent condition with almost daily symptoms. Chronic migraine (defined as occurring on 15 or more days per month) is accompanied in some individuals by both physiologic changes in pain perception and anatomic alterations within the brain.[103]

Table 6-22 **Symptoms of Migraine Headaches and Criteria for Diagnosis**

Migraine Phase	Symptoms
Prodrome	
Symptoms may or may not precede headache by several hours	Fatigue, depression, irritability, food cravings, yawning, muscle tenderness, neck stiffness, abnormal sensitivity to light, sound and smell
Migraine without Aura	
Symptoms present at least 5 times lasting 4-72 hours (untreated or unsuccessfully treated)	The following characteristics (≥ 2): Unilateral location Pulsating quality Moderate or severe pain intensity Aggravated by or causing avoidance of routine physical activity Symptoms during a headache (≥ 1): Nausea, vomiting or both Photophobia and phonophobia
Migraine with Aura	
Symptoms present at least 2 times	Symptoms listed above with fully reversible aura symptoms (≥ 1): Visual Sensory Speech and/or language Motor Brainstem Retinal The following characteristics (≥ 2):

	One aura symptom occurring gradually over > 5 minutes Individual aura symptom lasting 5–60 minutes One aura symptom is unilateral Headache accompanies or follows aura within 60 minutes
Postdrome	
Symptoms may or may not present after resolution of the headache	Feeling drained or exhausted, difficulty concentrating, stiff neck, mild residual head discomfort

Reproduced with permission from Deneris A, Allen PR, Hayes EH, Latendresse G. Migraines in women: current evidence for management of episodic and chronic migraines. *J Midwifery Womens Health* 2017;62(3):270-285.[114]

A number of lifestyle changes may improve the frequency of migraine. These modifications include the avoidance of substances that the individual can identify as headache triggers (e.g., cheese, alcohol, chocolate), stress reduction, and stable patterns of eating and rest.

Pharmacologic therapy is used to treat acute attacks (abortive therapy) or reduce the severity and frequency of subsequent episodic attacks (preventive therapy).[114] Abortive treatments for women with mild, infrequent cases of migraine, include NSAIDs taken in maximal doses, or acetaminophen (Tylenol) 1000 mg. Either type of medication may also be combined with caffeine in OTC preparations. Historically, the most common abortive therapies were ergotamine preparations such as ergotamine tartrate/caffeine (Cafergot). Ergotamine is teratogenic, so women of childbearing age must use an effective and reliable contraceptive method when using it, and women planning a pregnancy require a change in therapeutic management. Ergotamines are less frequently used today as more effective medications have been identified. The triptans, such as sumatriptan (Imitrex) and naratriptan (Amerge) are serotonin receptor agonists and are quite effective as abortive therapy. Triptans are available as oral, intranasal, oral disintegrating tablets, or subcutaneous formulations. The U.S. Food and Drug Administration (FDA) has issued a caution with regard to use of triptans and selective serotonin reuptake inhibitors (SSRIs) because both drug classes increase serotonin, which can place the woman at risk for serotonin syndrome. If the triptan is used infrequently, the risk of serotonin syndrome is very small.

Preventative therapy for migraine includes agents from a number of drug classes, such as the tricyclic antidepressants, antiepileptics, beta-blockers, calcium-channel blockers, ACE inhibitors, and angiotensin receptor blockers. Women requiring long-term migraine management should be under the care of a neurologist or another practitioner skilled in the management of headache.

Menstrual-related migraines may benefit from long-cycle combined hormonal therapy or progesterone-only contraception, particularly the levonorgestrel intrauterine system (IUS). Decreasing the frequency of estrogen withdrawal minimizes the headache response.[115] When estrogen is included in treatment, the woman should be monitored for possible increases in the frequency of headache, which would mandate the use of progesterone-only methods. Combined hormonal contraception is contraindicated in women who have migraine with aura, due to increased risk of stroke (Medical Eligibility Criteria for Contraceptive Use [MEC] category 4); among women who experience migraine without aura, the CDC considers the use of

combined hormonal contraception acceptable but not optimal (MEC category 2).[115] Additional discussion can be found in the *Hormonal Contraception* chapter. Short-term use of a triptan in the days prior to the menses may also interrupt the headache cycle. Midwives can care for women with migraines but to do so, additional education regarding different presentations, danger signs, drug effects and prescribing considerations is needed.[114]

Epilepsy

Epileptic seizures are transient excessive aberrant or synchronous neuron activity that causes physical signs or symptoms.[116] Diagnosis requires two unprovoked or reflex seizures more than 24 hours apart; or one such seizure and a likelihood greater than 60% that further seizures will occur within 10 years; or diagnosis of a syndrome that includes epilepsy as one of its features.[116]

The classification of seizure disorders is based on whether the seizures are generalized or partial, with these categories being further subdivided by specific patterns of associated symptoms. Generalized seizures are caused by significant activity in both lobes of the brain, and almost always involve changes in consciousness. Tonic–clonic seizures (grand mal), absence (petit mal) seizures, and brief myoclonic seizures are all examples of generalized seizure activity. Partial seizures may or may not involve alteration in consciousness; if this symptom is present, they are referred to as complex partial seizures.

Seizure activity in women of childbearing age may peak around the times of ovulation and menstruation, or less commonly with an inadequate luteal phase—a condition known as catamenial epilepsy.[117] The midwife's role in caring for women diagnosed with a seizure disorder is primarily focused on the effect of epilepsy medications on reproductive health, the management of contraception, and assessment of risks associated with epilepsy or medications used to treat epilepsy. Menstrual disorders, polycystic ovary syndrome, decreased libido, and infertility are all associated with epilepsy and with some antiepileptic medications.[117] Decreased bone mineral density has also been linked to the use of antiepileptic drugs, although the seizure-associated falls' contribution to overall fracture rates is not clear.[118] Some anticonvulsants are associated with an increased risk for teratogenic effects, and pregnant women on these medications should be referred to a genetic specialist for counseling. A review of preconception care for women with epilepsy can be found in the *Health Promotion Across the Lifespan* chapter.

Contraceptive management for women with epilepsy is complicated by the interaction of estrogen-containing hormonal products with antiepileptic medications that affect the cytochrome P450 metabolic pathway—for example, barbiturates, carbamazepine (Tegretol), lamotrigine (Lamictal), phenytoin (Dilantin), and topiramate (Topamax; in larger doses).[119] These medications may interfere with the effectiveness of hormonal contraceptives and increase the risk of unintended pregnancy. The contraceptive implant etonogestrel (Nexplanon) has also been shown to have an increased risk of failure among women taking these types of antiepileptic agents.[119] Both depot medroxyprogesterone acetate (DMPA) and the levonorgestrel-containing IUS (Mirena) are safe for use in women taking antiepileptic

therapies, as is the copper intrauterine device (ParaGard); however, some authorities suggest DMPA may need to be given at 10-week rather than 12-week intervals.[119] Use of a barrier method as a secondary method of contraception can be recommended. More information about contraception, including evidence-based criteria for eligibility, can be found elsewhere in this text. All women with epilepsy should receive counseling regarding risks associated with pregnancy, and referral to a maternal–fetal medicine specialist should be considered.

Another important concern among women with epilepsy is the increased risk of depression and suicide. Both the psychological and physical stresses of living with the disease and the side effects of medication factor into these risks.[120] Screening for mood changes and suicidal ideation during gynecologic or well-woman visits is particularly appropriate when caring for women with this disorder.

Carpal Tunnel Syndrome

The carpal tunnel carries the median nerve through the wrist, where compression from edema, inflammation of the tissue, or anatomic distortion can produce the classic symptoms of carpal tunnel syndrome (CTS)—tingling, numbness, or altered sensation across the palmar surface of part of the thumb, the first two fingers, and part of the ring finger in the affected hand. Over time, CTS almost always becomes bilateral. The woman may report that pain and numbness are worse at night. **Figure 6-5** illustrates the area affected by carpal tunnel syndrome.

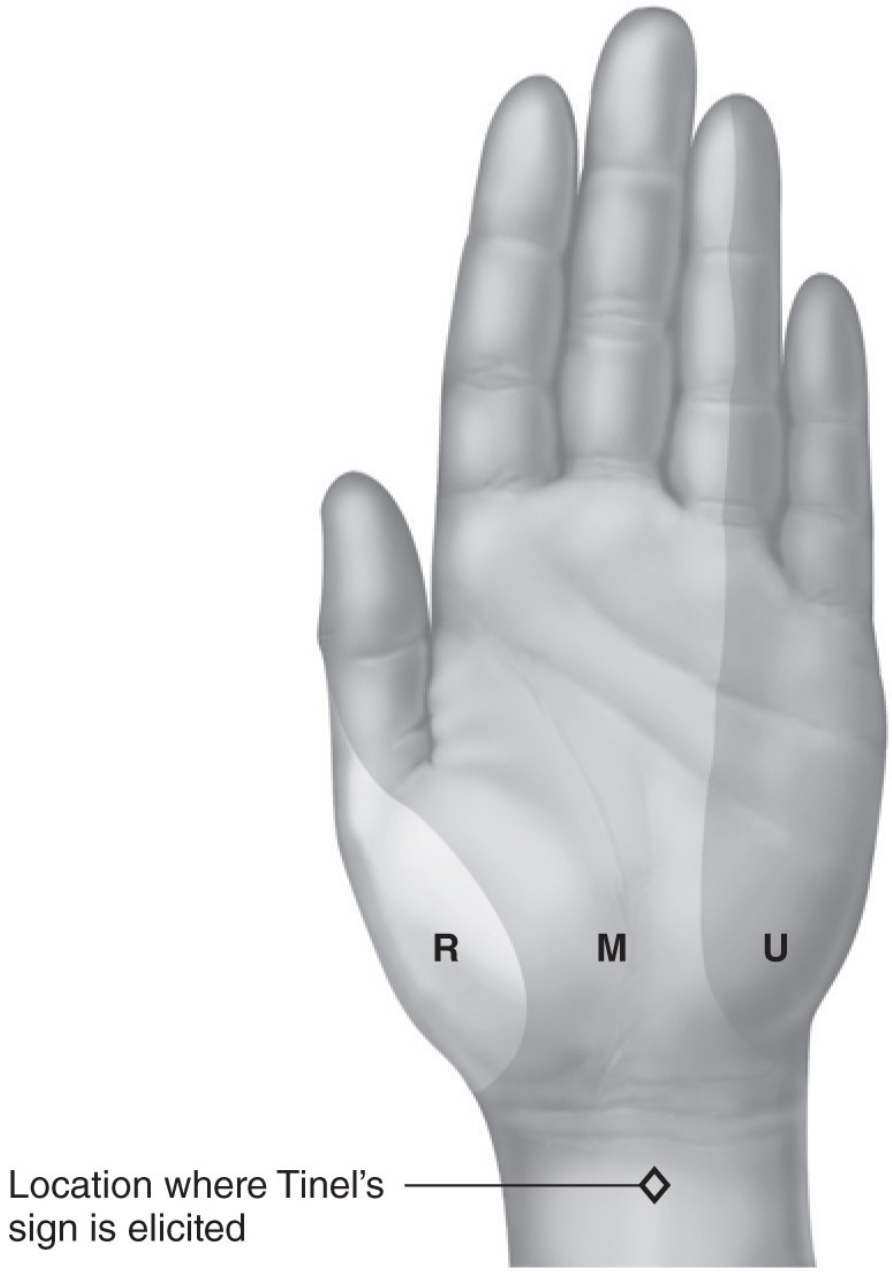

Figure 6-5 Distribution of sensation by the radial (R), median (M), and ulnar (U) nerves.

Female gender, pregnancy, increasing age, obesity, history of wrist injury or arthritis, diabetes, and hypothyroidism have all been associated with increased risk of developing CTS.[121] Recent research indicates that work-related activities play a significant role in the development of CTS.[122] When women engaged in a repetitive motion of the wrists report numbness or loss of sensation in this pattern, carpal tunnel syndrome is often assumed to be a causative factor. Other forms of nerve damage can also present with similar symptoms. If additional symptoms unrelated to the median nerve are present, prompt referral is warranted.

Two simple tests can help to confirm that the woman's report is consistent with carpal tunnel syndrome (**Figure 6-6**). First, tapping over the wrist crease in the midline should produce

tingling in the affected area; this is referred to as Tinel's sign (Figure 6-6B). Second, holding the wrist flexed for 45 to 60 seconds and releasing it should produce symptoms; this is referred to as the Phalen test (**Figure 6-6A**). Electromyography and nerve conduction studies will confirm the diagnosis of carpal tunnel syndrome.

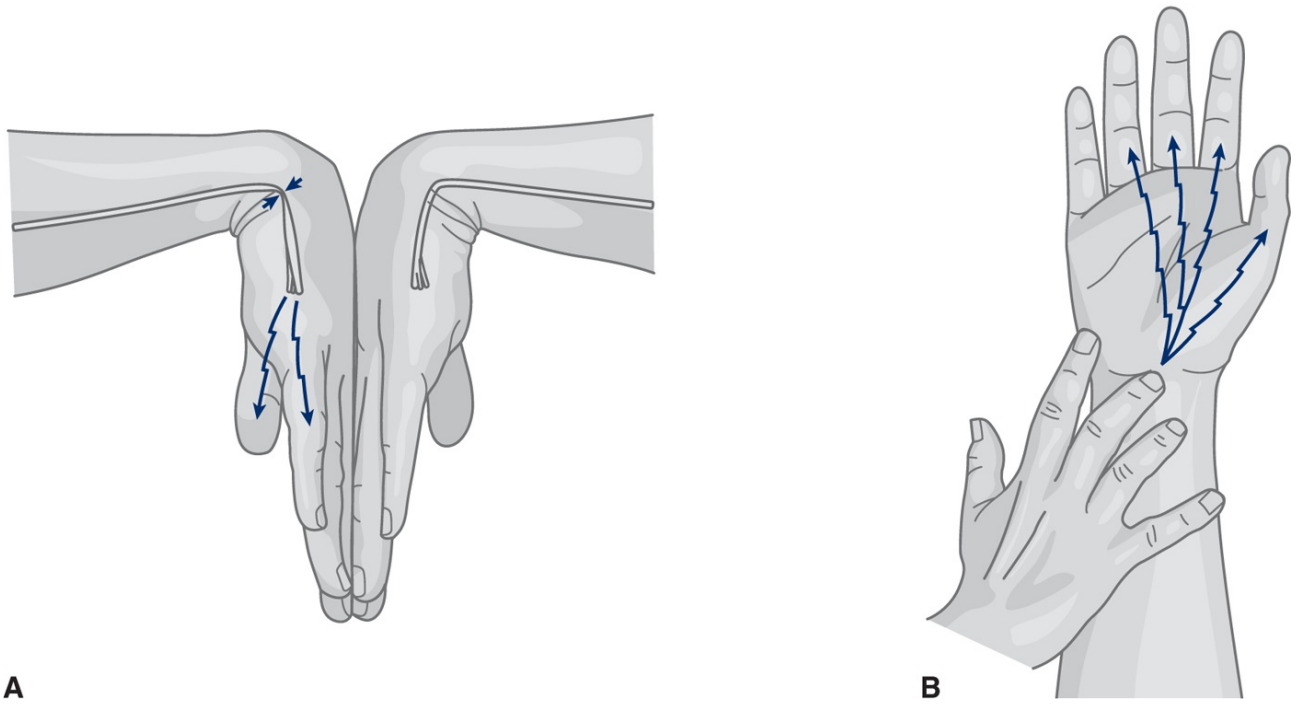

Figure 6-6 A. Phalen test. **B.** Tinel's sign.

Initial treatment is conservative, and may begin with splinting at night to place the wrist in a neutral position. Only limited evidence supports the effectiveness of this technique.[123] Other conservative therapies, ranging from nerve gliding techniques to wrist manipulation to yoga and aerobic exercise, have been recommended, but there is little evidence of their effectiveness.[124] If symptoms are severe, persist, or worsen with conservative management, the woman should be referred to an orthopedic surgeon or neurologist for further evaluation. Treatment may then include injections of steroids or surgical release of the nerve. If left untreated, the condition will worsen over time and eventually lead to permanent decrease in sensation.

Musculoskeletal Disorders

Sprains and Strains

Musculoskeletal complaints account for approximately 10% to 15% of primary care visits. A systemic approach to any complaint of musculoskeletal pain will help the midwife evaluate for the multiple differential diagnoses that are possible. When evaluating a woman for musculoskeletal pain, it can be helpful to have her point to the pain and describe any associated injury. The initial assessment includes determination of localized versus diffuse, acute versus chronic, and inflammatory versus non-inflammatory conditions. Sprains are stretched or torn ligaments; strains are stretched or torn muscles or tendons. **Table 6-23** compares common signs and symptoms of the two conditions.

Table 6-23 Differential Diagnosis for Sprain or Strain

Type of Injury	Symptoms
Sprain	Bruising over the joint
	Limited flexion/extension of joint
	Pain
	Swelling
Strain	Limited contraction/release of muscle
	Muscle spasm
	Pain
	Swelling

Sprains

The most commonly sprained joint is the ankle, with more than 600,000 ankle injuries occurring each year in the United States.[125] The knee, wrist, and thumb are other commonly injured sites. Twisting or overstretching a joint can cause the ligaments securing the bones to be stretched or torn. Once injured, a joint is prone to reinjury, possibly from persistent laxity in the ligament, or damage to the nerves and muscles associated with the joint. Approximately 20% of ankle sprains result in some degree of permanent instability.[126]

Sprains are graded based on degree of injury, as shown in **Table 6-24**.[127] Ankle stability can be evaluated using the talar tilt and anterior drawer tests (**Figure 6-7**). Normal inversion of the ankle is less than 35 degrees; normal plantar flexion is less than 50 degrees. Whenever evaluating the ankle, the opposite foot should also be assessed for comparison purposes, as there is significant individual variation in normal joint flexion. Diagnosis of an ankle sprain includes ruling out a fracture. The Ottawa rules used to determine the need for X ray of the ankle include the presence of pain near the affected ankle, and either tenderness on the posterior aspect or tip of the malleolus or inability to bear weight for at least four steps both immediately after the event and in the examining room.[127]

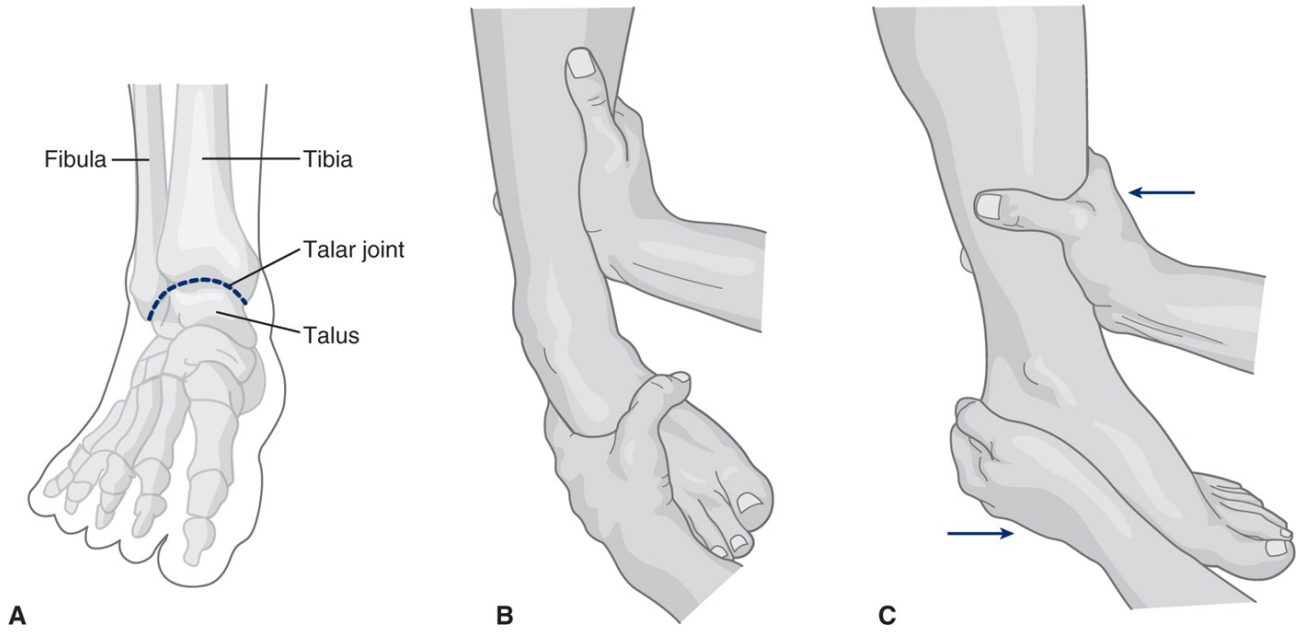

Figure 6-7 Talar tilt and anterior drawer tests to assess ankle sprain. **A.** Talar joint. **B.** Talar tilt. **C.** Anterior drawer test.

Table 6-24 **Sprain Grades**

Grade	Symptoms
Grade 1	Ligament is stretched; may have micro-tears Minimal swelling; full weight bearing possible No instability in the joint
Grade 2	Macro-tears but ligament remains attached Moderate swelling and bruising Difficulty with weight bearing Joint is unstable
Grade 3	Complete tear through the ligament Extensive swelling, bruising, and severe pain Unable to bear weight; significant joint instability

Based on Stiell IG, Greenberg GH, McKnight RD, et al. Decision rules for the use of radiography in acute ankle injuries: refinement and prospective validation. *JAMA.* 1993;269(9):1127-1132.[127]

The management of sprains is determined by the severity of the injury. NSAIDs and acetaminophen are generally sufficient pain medications for these conditions; use of opioids should be avoided. The immediate implementation of a strategy to limit bruising and swelling follows the mnemonic “PRICE”: protection, rest, ice, compression, and elevation (**Table 6-25**). Progressive rehabilitation of the joint is appropriate in all cases. Long-term immobilization is less useful than an approach that encourages exercises to strengthen the joint after 2 to 3 days.[128] Only the most severe sprains require surgical repair, following unsuccessful physical therapy.[126]

Table 6-25	PRICE: A Conservative Strategy for Management of Sprains and Strains
Strategy	**Management**
Protection	Use of an air splint, fixed-joint, or adjustable walking cast
Rest	Limitation of activity involving weight bearing
Ice	Applied intermittently for up to 20 minutes each time
Compression	Elastic bandages that limit swelling and extravasation into damaged tissue
Elevation	To the level of the heart

Strains

Strains are the result of over-stretching a muscle or tendon causing a tear; the degree of risk of an injury is related to the strength and conditioning of the individual, the level of activity, and the direction and intensity of the movement involved. The actual degree of muscle tearing, the resultant bleeding into the tissue, and inflammation all factor into determining the extent of injury. Clinical diagnosis is frequently all that is necessary in case of a strain; ultrasound or magnetic resonance imaging (MRI) may occasionally be required for further evaluation.

Similar to treatment of individuals with sprains, PRICE therapies are used for the first 3 to 5 days following strains, followed by gradual reintroduction of physical activity.[128] NSAIDs provide pain relief and decrease associated inflammation, and can be used as adjunctive treatment in the acute phase of tissue injury. Long-term use of NSAIDs may be associated with poorer tissue healing.[129]

Low Back Pain

Pain in the lower back, with or without sciatic nerve pain, is divided into acute pain lasting less than 7 weeks and chronic pain. The rate of low back pain in women has been reported as 30%.[130] Approximately 25% of all individuals who experience an episode of acute, nonspecific low back pain will have a recurrence within one year.[131] Risk factors include female gender, increasing age, obesity, smoking, psychological factors, and physically intensive work.[132] The differential diagnoses range from sprain/strain to spinal conditions that include herniated discs, compression fractures, spinal stenosis; systemic diseases including cancer and connective tissue disease; and referred pain from pelvic or abdominal disease.[133]

Assessment of the woman presenting with symptoms consistent with acute lower back pain includes history and related symptoms, her subjective evaluation of the pain, associated psychological factors, ability to function normally, environmental or work-related risks, prior episodes, and questioning regarding red-flag symptoms of more serious disorders. Red-flag signs and symptoms include history of trauma, parenteral drug use, unexplained weight loss, cancer history, long-term use of steroids, fever, incontinence, and intense localized pain on physical examination.

Clinical assessment does not require imaging for acute, episodic low back pain.[134] Instead,

MRI is required only for those individuals with progressive neurologic deficit. The assessment should allow for differentiation of pain into nonspecific causes, possible radiculopathy or stenosis, and other risks including progressive neurologic disease.[134]

Initial management of acute low back pain includes health education about exercise, encouragement to remain physically active, nonpharmacologic measures, and pharmacologic management. Heat may offer relief from strains. Bed rest or prolonged immobilization is of no additional benefit in caring for women with acute low back pain.[134,135]

Pharmacologic therapy for acute low back pain begins with NSAIDs or acetaminophen (Tylenol). Short-term use (fewer than 4 days) of a muscle relaxant can assist when acute pain is severe. No strong evidence exists to recommend one agent over the others, although cyclobenzaprine (Flexeril) is commonly recommended.[134,135] While opiate medications can be effective pain relievers, their benefit in treating low back pain is often outweighed by their potential for abuse. Prolonged use of opiates occurs frequently and is associated with higher rates of adverse outcomes, including slower recovery, addiction, overdose, and accidental death.[136] Among women with chronic low back pain, tricyclic antidepressants have been shown to offer some benefit.

Nonpharmacologic therapies have also shown some benefit in the treatment of individuals with chronic low back pain. Cognitive-behavioral therapy, spinal manipulation, acupuncture, massage, and yoga, as well as interdisciplinary approaches, have all demonstrated moderate to significant benefits.[134,135]

Dermatologic Conditions

When assessing a skin lesion or rash, a history specific to the current concern, including the pattern of recurrence, timing and progression, and potential environmental exposures, will facilitate identification of the dermatologic condition. The physical examination includes assessment of the appearance, shape, and texture of the lesion; the pattern of multiple lesions; and distribution of lesions across the body. Knowing the terminology for common skin changes standardizes descriptions and facilitates identification; such terms are identified in **Table 6-26**. Several of the more common or significant conditions found during the delivery of primary care to women are described in this section.

Table 6-26 Terms and Definitions for Common Skin Manifestations

Term	Definition
Acne	A dermatologic condition primarily of the sebaceous skin glands characterized by papules, pustules, or comedones. This condition is more properly termed acne vulgaris to differentiate it from other, less common types of acne.
Actinic keratosis (AK)	A premalignant skin condition with multiple crusty patches. Also termed solar keratosis.
Calcineurin inhibitors	Immunosuppressant agents that are theorized to act by selectively inhibiting inflammation through action on T-cell activation.
Carbuncle	A skin infection composed of a cluster of boils (furuncles). This infection is most frequently caused by *Staphylococcus aureus*.
Cellulitis	An acute spreading dermatologic bacterial infection characterized by significant edema, erythema, and pain.
Cosmeceutical	A word coined from the terms “cosmetic” and “pharmaceutical,” which is used to describe agents that both have therapeutic effects and promote attractiveness.
Dermatophytes	Parasites that may infect the skin. An example is athlete’s foot.
Eczema	Inflammatory dermatologic process that is characterized by pruritus, erythema, and lesions that may be encrusted and scaly.
Furuncle	Skin infection commonly involving a hair follicle. Also called a boil.
Humectant	Agent that absorbs water and promotes maintenance of moisture on the skin.
Intertrigo	Rash or inflammation of the body folds or intertriginous areas of the skin.
Keratinocyte	Epidermal cell that synthesizes keratin.
Langerhans cell	Dendritic skin cell that transports antigens to lymph nodes.
Melanin	Skin pigment produced by special cells (melanocytes).
Melanocyte	Cell located in the bottom layer (stratum basale) of the skin’s epidermis that produces melanin.
Merkel cell	Cell found in the middle layers of the skin around hair follicles. Cancer originating among these cells—Merkel cell carcinoma—tends to be highly aggressive.
Onychomycosis	Fungal infection of the nails on either the fingers or the toes.
Psoriasis	Skin condition caused by overgrowth of keratinocytes, resulting in patchy thickened skin.
Pyoderma	Skin condition characterized by purulent filled lesions.
Retinoids	Natural or synthetic derivative of vitamin A that is widely used in pharmacotherapeutics in dermatology.
Seborrheic	Wart-like, benign skin lesions.

keratoses	
Solar lentigo	Flat pigmented lesions on sun-exposed skin. Also known as senile lentigo.
Sun protection factor (SPF)	A measure of the degree to which a sunscreen provides protection from the sun's ultraviolet rays. A sunscreen with an SPF factor of 15 or greater is recommended by the American Academy of Dermatology.
Telangiectasia	Thread-like red lines on the skin, often seen in clusters and referred to as "spider veins." Thought to be caused primarily by exposure to the sun and extreme temperatures.
Xerosis	Dry skin.

Atopic Dermatitis (Eczema)

Initial signs of atopic dermatitis most often occur during infancy, and develop progressively throughout the years into adulthood. Much of the data on the prevalence of atopic dermatitis and eczema are based on pediatric data. However, a survey of adults found that more than 10% reported symptoms consistent with eczema and 6% met the more stringent definition of atopic dermatitis.[137] Living in urban areas, black race, and higher educational status among adults in the household all contribute to increased risk; higher family income is inversely associated with risk.[137,138]

Both genetic and environmental factors contribute to the development of symptomatic disease. Among the environmental triggers are aeroallergens such as pets and dust mites, and food sensitization, particularly to milk or eggs. Skin bacteria (such as *S. aureus*) and fungi (including *Malassezia* species) are also involved in development of atopic dermatitis.[139] Hypersensitivity to a variety of irritants, including chemicals, rough fabrics such as wool, humidity, or temperature change, helps account for the pruritus associated with atopic dermatitis. Finally, increased stress is associated with worsening symptoms of atopic dermatitis.

Management of atopic dermatitis consists of the application of emollient creams, possible use of moderate-strength topical corticosteroids, or topical calcineurin inhibitors (tacrolimus [Protopic], pimecrolimus [Elidel]). When secondary bacterial infections occur, topical antibiotic treatment for short periods may be recommended; long-term use of topical antibiotics may lead to resistance and should be avoided. In addition to medication, education about maintenance use of emollients, avoidance of triggers, and stress reduction are important components of care. Referral to a dermatologist for development of a long-term plan of care often is indicated.

Psoriasis

Psoriasis is a chronic skin disorder caused by an underlying immune defect that produces thick pruritic, scaly plaques on the skin. Commonly the head and neck, elbow and knee joints, and lower back are affected. Although lesions can occur anywhere on the body, the extremities are more often affected than the trunk. The prevalence of psoriasis in the United States is reported to be approximately 2% to 3% of the population, with the incidence of new cases peaking among young adults.[140] Among the various expressions of psoriasis, plaque psoriasis accounts

for almost 90% of all cases. In this form, well-defined areas of thickened, erythematous skin with silvery, scaly patches are seen, usually with symmetric distribution.

Women in whom psoriasis is suspected should be referred to a dermatologist for evaluation and plan of care. For women whose plaques cover less than 5% of the body surface, topical therapy may be sufficient, although this treatment rarely is associated with complete remission. Initial topical treatments include corticosteroids, salicylic acid (to soften keratinized skin), and moisturizers. Ultraviolet light therapy, retinoids, methotrexate (Trexall), cyclosporine-A (Neoral, Sandimmune), and biologic agents are used both for more severe cases and for more complete healing.[141]

Psoriasis is a complex condition that may remit, but rarely resolves. It has been associated with a number of comorbidities, including metabolic syndrome, cardiovascular disease, and autoimmune disorders. Associated psychological conditions include depression and suicidal ideation.[141] Ongoing assessment of depression status and stressors is an important part of providing care for women who have psoriasis. Counseling can include use of stress reduction techniques and comfort measures such as oatmeal baths.

Skin Cancers

Unprotected exposure to ultraviolet radiation is directly related to development of malignant melanomas and other skin cancers, as well as precursor lesions such as actinic keratosis, squamous cell carcinoma, and basal cell carcinoma. Exposure may occur via natural sun or a tanning facility. All of the skin cancers share the risk factors of fair skin with a tendency to freckle or burn, blond/red hair, blue or green eyes, history of severe sunburns, immunosuppression, and family history. Each year, more than 3.3 million persons in the United States are estimated to be diagnosed with a non-melanotic skin cancer.[142] Prevention of and screening for skin cancers is addressed in detail in the *Health Promotion Across the Lifespan* chapter.

Several types of skin cancer are discussed here to provide midwives with an understanding of abnormal findings on examination of the skin. The diagnosis and management of skin cancers is beyond the scope of practice for midwives. All women with suspicious skin lesions should be referred to a dermatologist for further evaluation and treatment.

Actinic Keratosis

Actinic keratoses are small, dry, rough textured papules or plaques caused by excess exposure to ultraviolet (UV) radiation. In the United States, as much as 25% of the population may develop actinic keratoses over a lifetime, with those older than 40 years being at increased risk. Early actinic keratosis lesions are usually smaller than 2 cm; they may remain the color of the underlying skin, or be gray or pink. Over time, actinic keratoses may progress to a harder, warty texture. There is disagreement about whether actinic keratosis is itself a precancerous lesion or a squamous carcinoma in situ.[143]

Basal Cell Carcinoma/Squamous Cell Carcinoma

Basal cell carcinomas have a waxy or translucent appearance with a raised edge and central erosion. Risk factors for basal cell carcinoma include skin injuries such as old burns or scars, inflammation, radiation therapy, arsenic exposure, and skin ulcers.[142] Like actinic keratoses, squamous cell carcinoma is scaly, but the lesions will be thickened, poorly defined, occasionally hard (horn-like), on an erythematous base. In addition to the specific risk factors for basal cell carcinoma cited earlier, cutaneous human papillomavirus (HPV) infection and a history of actinic keratoses are factors that increase the risk of squamous cell carcinoma.

Melanoma

The incidence of melanoma has been steadily increasing in the United States; the lifetime risk is approximately 3%, with the highest rates found among Caucasians.[144] Unlike the other skin cancers, which are relatively easy to treat and have excellent prognoses, melanoma has an increased risk of metastasis. Disease-free survival depends on early diagnosis and prompt surgical excision. Five-year survival rates for individuals diagnosed with a localized tumor are greater than 90%; by comparison, metastatic disease has a 5-year survival rate of only 15%.[145]

Melanoma is more common among women with large numbers of moles, and among women with dysplastic nevi. Dysplastic nevi are larger than common moles, with a rough texture, often irregular in outline, and of different colors. Among women, melanomas are more common on the legs and trunk. Lesions also can appear on the genital area, and they should be carefully noted for follow-up. The midwife should initiate a referral to a dermatologist for any woman with a suspicious lesion.

Common Skin Infections

Herpes Zoster

Herpes zoster, also called shingles or zoster, is a reactivation of the varicella virus (chickenpox) as immunity to the virus wanes. This virus lies dormant along one or more dermatomes, in the dorsal root of sensory nerve ganglia. Approximately 1 million cases of zoster occur in the United States annually. The incidence rises with age and in persons in whom cellular immunity is impaired. Other risk factors are unclear, but some studies report female gender as a risk factor.[146] The incidence of zoster among whites is approximately twice that among African Americans.[147] Physical trauma at the affected dermatome and psychological stress may also play a role in the reactivation of varicella virus.

Clinically, zoster often presents with a prodrome of burning pain along the affected dermatome, accompanied by headache, fatigue, and malaise. The typical painful rash of papules on an erythematous base that progresses to vesicles, ruptures, and crusts over may take 7 days to develop. The entire cycle from initial rash to complete healing takes 2 to 3 weeks.

Management of acute herpes zoster includes antiviral drugs such as acyclovir (Zovirax) or valacyclovir (Valtrex), with the addition of analgesics to treat the pain. Initially, acetaminophen (Tylenol) or an NSAID should be given, with opioids being reserved for severe or intractable pain. When postherpetic neuralgia develops, severe pain may persist for

months. Treatment of women with postherpetic neuralgia is complicated and requires referral to a pain specialist.

Transmission from direct contact with lesions is possible, but such contact will produce chickenpox, not herpes zoster. Only those persons who have not been vaccinated or who have not experienced prior varicella infection are at risk for chickenpox. Unlike with chickenpox, droplet transmission does not occur with zoster. Vaccination against herpes zoster is now recommended for adults age 60 years or older.[147] Such vaccination reduces the likelihood of ever having an outbreak by more than 50%, and is described in detail in the *Health Promotion Across the Lifespan* chapter.

Herpes Simplex Labialis

The herpes simplex labialis virus (HSV-1) is most commonly transmitted nonsexually and during childhood. Many cases of HSV-1 infection are subclinical, diagnosed only by serology; many individuals do not realize that their cold sore is, in fact, a herpes lesion.[148] Direct exposure of mucous membranes or abraded skin to viral shedding is required for transmission of HSV-1. However, the virus can be shed asymptomatically and can be transmitted by droplet or persist on skin or objects for brief periods of time.

After initial exposure, the development of symptoms depends on the inoculum—that is, the amount of virus to which the individual was exposed—and may occur up to 3 weeks after exposure. The first HSV-1 outbreak, which is typically the most widespread and painful, lasts for 10 to 14 days. Clusters of 1-mm to 2-mm painful vesicles develop on an erythematous base and open to create ulcerative lesions. Lymphadenopathy and flu-like symptoms often accompany a primary outbreak. Pain may be severe enough to lead to avoidance of food and fluids, thereby producing dehydration.[149]

Herpes viruses enter a latent state in the nerve ganglia after the initial infection. Recurrent outbreaks are typically briefer and milder, moving through the stages of prodrome, lesion formation, ulceration, and crusting within 3 to 4 days. Complete skin healing can take an additional week.[150] In addition to causing oral lesions, HSV-1 can infect other locations including the eye (herpes keratitis), fingers (herpetic whitlow), and genital region.[149,151]

Management of primary oral lesions includes acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir) for 7 days; the use of a topical anesthetic; and fluid/nutritional supplementation when needed.[150,152] Promptly providing oral antiviral treatment for recurrent lesions can reduce shedding and duration of lesions; topical products, however, have not been shown to have the same benefit. Single-day therapy can be prescribed in the form of either valacyclovir (2 g twice in 24 hours) or famciclovir (1500 mg once); acyclovir requires multiple doses over 5 days, but can be used if other medications are not accessible. Suppression therapy with acyclovir 400 mg twice daily, valacyclovir 500 mg or 1 g daily, or famciclovir 500 mg twice daily can be provided if the woman experiences frequent recurrences.[150,152]

Tinea Versicolor (Pityriasis)

Tinea versicolor is a chronic infection, in which normal skin fungi that are present on the outer layer of the epidermis, in hair follicles and sebaceous glands, overgrow and become pathogenic. Factors that increase the risk for outbreaks include heat and humidity; oily skin; other conditions including steroid therapy, immune suppression, malnutrition, burns, adrenalectomy, and Cushing's disease; and oral contraceptive use.

The associated rash consists of flat macules of discolored skin on the neck, upper back, or chest. Light-skinned individuals will notice hyperpigmented lesions, while those with darker skin may notice either hypopigmented or hyperpigmented lesions. The macules spread to form large patches, and pruritus may be associated with outbreaks.

Topical antifungals, including clotrimazole (Lotrimin, Mycelex) and ketoconazole (Nizoral), can be applied daily for 2 to 4 weeks. Ketoconazole shampoo (Nizoral) can also be used daily for 3 days as a body wash from the scalp to the hips. When the spread of the rash is extensive or treatment with topical medications proves ineffective, a course of oral antifungals can be prescribed. The affected woman should be advised that the presence of tinea versicolor is not secondary to poor hygiene, and that she needs to continue the prescribed treatment even if lesions resolve during therapy. She also may have areas of hypopigmentation when tanning until the melanocytes destroyed by the fungus have become reestablished.

Bacterial Skin Infections

Bacterial skin infections are a common reason for healthcare visits. Knowledge of the presentation of the most common bacterial skin infections informs proper management of these conditions. Among the normal skin flora, *Staphylococcus epidermis* and *Staphylococcus aureus* are the most common bacteria, along with the corynebacteria and mycobacteria; *Streptococcus pyogenes* is less common. The most significant pathogens within this group are *S. aureus* and *S. pyogenes* (group A beta-hemolytic *Streptococcus*). Risk factors for the development of cellulitis and other soft-tissue infections include trauma, bite injuries, prior cellulitis, diabetes, comorbidities that damage the venous or lymphatic systems, chronic renal disease, cirrhosis, and intravenous drug use.

Impetigo

Impetigo is a superficial infection that produces small vesicles on an erythematous base that open and crust; these vesicles are most often found on the mouth, nares, and arms. If left untreated, the infection may spread and can persist for weeks. Mupirocin (Bactroban) ointment applied three times daily is first-line therapy for individuals with small numbers of lesions. Oral antibiotics should be used for resistant or widespread infection.[153]

Erysipelas

The most likely source of erysipelas is infection with *S. pyogenes*. This infection most often presents as a superficial infection of the skin producing a painful erythematous plaque with well-defined edges. It is treated similarly to cellulitis.[153]

Cellulitis

Penetration of fluid into subcutaneous tissue, causing erythema, warmth, edema, pain, and possibly lymphadenopathy, is the hallmark of cellulitis. An elevated white blood cell count and fever may be present. When ulcers or other open lesions are present, *S. aureus* infection is the likely culprit. By comparison, diffuse infection occurs more commonly when *S. pyogenes* is the pathogen present.

Both erysipelas and cellulitis usually are treated orally with penicillinase-resistant semi-synthetic penicillin (e.g., dicloxacillin [Dynapen]), cephalosporin (e.g., cephalexin [Keflex]), or clindamycin (Cleocin). When systemic symptoms are present, infections require parenteral therapy.[153] When purulent cellulitis is present, treatment should include an antibiotic effective against methicillin-resistant *S. aureus* (MRSA). When cellulitis or erysipelas do not resolve with antibiotic treatment, the woman should be referred to a specialist for further assessment.

Purulent Soft-Tissue Infections

Conditions such as furuncles and carbuncles are most commonly found in areas of the body where restrictive clothing is worn or chafing occurs. A small, firm, red papule will enlarge and become painful as pus increases inside, then may either resolve or open and drain spontaneously. When several furuncles coalesce into a carbuncle, the affected individual may experience systemic symptoms of fever or chills in addition to the local pain. Carbuncles will become fluctuant, thinning the skin above the site and drain, possibly from several openings. Treatment of women with sporadic lesions can be accomplished with warm soaks to help open and drain the site. More severe lesions may require incision and drainage. Treatment with trimethoprim–sulfamethoxazole, clindamycin, or doxycycline is appropriate.[154]

Necrotizing Soft-Tissue Infection

Necrotizing fasciitis is a soft-tissue infection caused by secondary or polymicrobial extension of a surface infection, often involving mixed anaerobes or group A *Streptococcus*. The infection encompasses the subcutaneous tissue and extends to the muscle layer. In 80% of cases, there is a direct relationship to a skin lesion.[153] To distinguish cellulitis from a necrotizing infection, the following signs and symptoms can be identified in necrotizing infections: severe pain, development of bullae, skin bruising, rapid progression to systemic symptoms, edema, surface anesthesia, and a wooden or rigid texture to the underlying tissue.[153] Any suspicion of deep-tissue infection associated with a skin lesion should result in an immediate referral of the woman to a physician, urgent care, or an emergency department to be evaluated for antibiotic and possible surgical treatment.

Methicillin-Resistant Staphylococcus aureus

S. aureus is one of a group of common bacteria—including *Enterococcus*, *E. coli*, and *Neisseria gonorrhoeae*—that have developed increasing resistance to the traditional antibiotic therapies. More than half of all serious skin and soft-tissue infections are now caused by

MRSA.[155] In office settings, MRSA is most commonly seen as boils or carbuncles. These lesions begin with a “spider bite” appearance before enlarging and becoming painful.

The Infectious Disease Society of America’s guidelines continue to recommend incision and drainage of boils as the most appropriate treatment. Its recommendation is to defer antibiotics unless the individual has cellulitis or severe disease with multiple locations. If MRSA is suspected, antibiotics that offer adequate coverage, including TMP-SMX (Bactrim), clindamycin (Cleocin), a tetracycline, or linezolid (Zyvox), should be prescribed for 5 to 10 days, and a culture taken prior to treatment.[155] Regardless of the midwife’s choice to use supportive measures, incise the lesion for drainage, or prescribe antibiotics, women should be advised that signs of worsening infection or failure to begin healing are indications to seek further care.

Substance Use: Screening and Counseling

Screening for alcohol, tobacco, and substance use can be an uncomfortable process. As with questions about sexuality or abuse, some positive answers may lead to a discussion the midwife feels poorly prepared to address.

All women should be screened for tobacco use and alcohol misuse; counseling interventions should be provided for women who use tobacco and for whom alcohol misuse is suspected. A detailed discussion of screening for these conditions, including recommended screening tools, is provided in the *Health Promotion Across the Lifespan* chapter. Counseling interventions aimed at smoking cessation and reducing alcohol misuse are also provided in that chapter.

Screening for Substance Use

Screening for illicit or prescription drug overuse is not currently recommended as a standard screen for all adults in the United States by some organizations, but is recommended by others. Screening may be particularly important in some geographic locales. Screening for illicit drug use can be performed with any of several validated tools. However, legal and social complexities abound. Who should be screened? At what intervals? For which indications? If medical marijuana (or recreational marijuana) is legal in the state, how does that affect counseling about the risks? What about women with chronic pain? All of these issues should be considered and clearly described, both in practice guidelines and to women coming to the practice. Consent for drug testing should always be obtained.

Two areas of specific concern for every midwife are marijuana and opioid use: marijuana because it is transitioning from an illicit drug to a legal one, and opioids because of the epidemic at the intersection of heroin and prescription abuse. If screening is performed, it should be performed for all individuals. The National Institute of Drug Abuse (NIDA) quick screen starts with asking, “In the past year, how often have you used [fill in substance]?” The answer then leads the provider to follow-up questions and responses. The NIDA screen can be found in the Resources section at the end of this chapter.

Marijuana

Marijuana is the most frequently used illicit drug in the United States, as well as being a legal medication in an increasing number of jurisdictions and being legal for recreational use in a few states. Like alcohol use, marijuana use carries health risks as well as benefits. Those risks include development of substance use disorder, increased risk of psychosis, respiratory disorders, cardiovascular disease, and both short-term and cumulative declines in memory and attention.[156–158] Moreover, at least 1 in 10 marijuana users will develop addictive behavior.[157] Assessing women for use or misuse of marijuana can be done similarly to the way in which alcohol misuse is evaluated.

Opioid Use

Overall, 6 of 10 drug overdoses in the United States are now opioid related.[159] Moreover,

81% of cocaine overdose fatalities have opioids as a contributing factor.[160]

Even without the risk of overdose, prescription opioid use has both significant economic and health costs. These include the direct costs of excess prescriptions, lost days of work, and drug-related comorbidities.[161] A number of proposals have been made, and some states have enacted laws, to help reduce the risk of such use. Most states have implemented changes in health policy in an attempt to address the opioid epidemic, including mandating provider participation in prescription drug monitoring programs, making naloxone widely available, and limiting the way opioid prescriptions are written and filled. Professional organizations have also published guidelines that promote the use of NSAIDs and other non-opioid options for managing moderate pain; these measures are intended to decrease the risk of promoting dependency.[159,162] The Substance Abuse and Mental Health Services Administration (SAMHSA) provides an opioid overdose prevention toolkit with recommendations for prescribers and individuals.[163]

One contributor to the opioid epidemic is healthcare provider diversion—that is, the diversion of opioids to patients through the inappropriate provision of opioid prescriptions.[164] Halting inappropriate opioid-prescribing practices is an important first step in the fight against opioid use. Steps that individual prescribers can take include participating in prescription drug monitoring programs, limiting initial opioid prescriptions to immediate-release medications in the lowest dose, and prescribing the smallest number of doses that are consistent with pain guidelines and the anticipated need.[162] Seven-day limits for initial opioid prescriptions for acute pain should meet most individual requirements. Non-opioid alternatives and nonpharmacologic approaches to pain management should be provided and encouraged, along with health education about risks and benefits for each. When requests for opioid refills are made, the woman should be evaluated, as most midwives will not manage chronic pain conditions.

Conclusion

Modern midwifery has often been viewed as possessing a limited, albeit well-recognized, scope of practice—that is, midwives take care of healthy pregnant women and help them give birth. Historically, however, midwives have never limited their care exclusively to healthy pregnant women, if for no other reason than that many of the women traditionally served by midwives were at risk because of age, socioeconomic status, or lack of access to other healthcare resources. In addition, midwives have often provided first-line care for women and sometimes larger populations. As has always been true, the needs of the community and the skills of the midwives who serve that community help define midwifery scope of practice. Today midwifery is practiced in a healthcare system in which the only provider whom many women see is their "women's health" provider. While midwives still care for pregnant women, they are also obliged to correctly identify common conditions, minor and major, and facilitate treatment of women with these conditions by themselves or through other strategies such as collaborative management and referral.

Midwives must be able to describe abnormal or unusual symptoms or signs accurately, even when they cannot make a diagnosis with any certainty. These professionals must be prepared to assess and triage women with these conditions, and determine which can be managed autonomously by the midwife and which cannot. All midwives need to know to whom they will refer cases beyond their personal or professional scopes of practice. Referral can be to nurse practitioners or physician assistants, as well as to physicians, dieticians, social workers, physical therapists, and others. Creation of a large network of healthcare contacts serves both midwives and women well.

The astute reader may have noticed the frequency with which reference has been made to lifestyle changes that can help prevent or treat diseases. One of the assets that midwives bring to primary care for women is an understanding of the importance of health maintenance and disease prevention. Every midwife has the ability and responsibility to provide this aspect of primary care for all women.

Finally, the importance of combining an evidence-based approach with a holistic awareness of the various factors playing into the woman's life is increasingly recognized as positively influencing an individual's ability to adhere to treatment recommendations, whether these recommendations focus on lifestyle changes, medication, or other therapeutic interventions. The provision of effective health care requires an awareness and assessment of how poverty, insurance coverage, literacy, mental health, and other factors affect a woman's ability to achieve the goals she has set with the midwife from whom she obtains care.

Nutrition and Health

Health and nutrition are intimately interrelated. Proper nutrition is essential to human growth, development, and well-being. Increasing attention to the role of the body's microbiome, especially in the gastrointestinal tract, in metabolic, cellular, and neurologic functioning has in turn increased our knowledge about the direct connection between what we eat and our health.[1] Since the average woman can expect to live until at least 80 years, women should be aware of the growing body of evidence that suggests a healthy diet can prevent a number of detrimental conditions, such as cardiovascular disease (CVD), cancer, adult-onset diabetes, osteoporosis, and age-related vision loss. Measures to reduce this disease burden are relatively simple and well researched: maintaining a healthy weight; eating a well-balanced, nutritious diet; not smoking; and exercising regularly. Unfortunately, instead of adopting healthier diets and lifestyle choices, more than 36% of women in the United States today are obese,[2] and since 2009, women have decreased their fruit and vegetable intake and increased their moderate alcohol intake.[3]

For midwives to promote changes that counter these negative trends, nutrition counseling should be incorporated into regular practice. Such health education can help women distinguish among the myriad sources of dietary advice. In addition, women need to understand some basic principles of nutrition, appreciate the physiologic response of the body to ingested food, and be familiar with current evidence-based dietary guidelines. Healthy nutritional intake is essential in all phases of life, including pregnancy, and the key principles remain the same for women whether they want to lose weight, to gain weight, or to maintain their weight. The basics of nutrition and how foods consumed affect normal physiology are discussed in this chapter. Although understanding individual components of the diet is important for health professionals, counseling women about diet should be positively focused on types of preferable foods to eat and the need to eat a variety of foods, rather than on individual macronutrients and micronutrients.

Principles of Nutrition and Nutrient Recommendations

Nutrients are the chemical components of food. Humans require more than 40 different nutrients for good health. These nutrients are classified as either macronutrients (fats, carbohydrates, and protein) or micronutrients (vitamins and minerals). Water is also a necessary nutrient, but it does not fit into either category. Water, vitamins, and minerals provide no calories but are necessary, although not totally sufficient, for the body to be able to utilize the energy provided by fat, carbohydrates, and protein.

Vitamin and mineral supplements have become increasingly popular in recent years, and some women incorrectly think these agents can supply all needed nutrients. Ideally, humans should obtain both macronutrients and micronutrients from a diet composed of a variety of foods rather than from nutritional supplements. This diet must be balanced in a way that prevents nutritional deficiencies and excesses. Variety is essential both to guarantee proper intake of all necessary nutrients and to benefit from the protective effects of certain dietary components against diseases such as cancer and heart disease. Today's research suggests that

decreased health risks associated with a healthy diet are due to combinations of substances in foods and food groups rather than to the effect of any single substance or nutrient.

Nomenclature for Nutritional Standards

The U.S. Dietary Guidelines for Americans is updated regularly and the most recent eighth edition was published in 2015.[4] The 2011 update to the United States Dietary Guidelines, for the first time took a crucial step in recognizing that it is more important to emphasize the *types of foods* people should eat, rather than concentrating on the *individual nutrient levels* they should consume.[5] Nevertheless, labeling on packaged foods regarding the overall nutritive value of a product can still be useful. Therefore, it is important to be familiar with the nomenclature used by various U.S. governmental organizations for nutritional standards setting.

U.S. nutritional standards have two origins: the Health and Medicine Division (HMD) of the National Academy of Medicine (formerly the Institute of Medicine [IOM]) Food and Nutrition Board[5] and the Food and Drug Administration (FDA).[6] The Food and Nutrition Board standards were originally developed during World War II as part of an effort to ensure adequate nutrition for members of the armed services. Since then, these standards have been used to set government policy related to food programs such as the School Lunch Program and food relief efforts globally. The FDA guidelines are more recent and are intended to assist consumers in obtaining recommended nutrients in their diets.

Table 7-1 compares the terms used by the HMD's Food and Nutrition Board and by the FDA.[5,6] An important characteristic of the Daily Reference Intakes (DRIs) is that they not only aim to determine minimum nutrient intake levels necessary to prevent nutritional deficiencies, but also strive to set standards to decrease the incidence of chronic diseases such as osteoporosis and cancer.

Table 7-1	U.S. Nutritional Standards
Food and Nutrition Board, Health and Medicine Division, National Academy of Medicine	
Dietary Reference Intakes	
DRIs aim to determine minimum nutrient intake levels necessary to prevent nutritional deficiencies, and set standards to decrease chronic diseases such as osteoporosis and cancer. This term has more or less supplanted RDAs.	
DRIs are a combination of RDAs and AIs.	
DRIs also specify tolerable UL, RDAs, EAR, and AIs:	
Tolerable UL	
The maximum level of daily nutrient intake that is unlikely to pose risks of adverse health effects to almost all of the individuals in the group for whom it is designed.	
RDAs	
Developed and updated periodically.	
Set the recommended average intake over a 3- to 7-day period for each nutrient specified.	
Fewer than half of the more than 40 necessary nutrients have an established RDA.	
RDAs are set quite high to meet the needs of almost all (97–98%) individuals in a group, so they may be too high for individual needs.	
EAR	
The intake value that is estimated to meet the requirement defined by a specified indicator of adequacy in 50% of an age- and gender-specific group. At this level of intake, the remaining 50% of the specified group would not have their	

needs met.
AIs
Used to develop a recommended intake when a scientific basis for establishing the EAR is lacking.
Food and Drug Administration
DVs
DVs appear on FDA-regulated products.
DVs are not meant to set levels of nutrients to be consumed every day, but rather to help determine how particular foods fit into an overall healthy diet.
DVs are calculated based on a diet of 2000 calories per day (unless otherwise stated).
DVs are calculated from two sources—DRVs and RDI:
DRVs
Recommended proportions of protein, carbohydrate, and fat in the diet.
Recommended grams per 1000 calories of dietary fiber intake.
Recommended daily maximums for sodium and potassium.
RDI
To ensure that the nutritional needs of all age groups are met, the RDI is calculated from the highest DRI for each nutrient.

Abbreviations: AIs, adequate intakes, DRI, dietary reference intake; DRV, Daily Reference Value; DVs, Daily Values; EAR, estimated average requirement; FDA, U.S. Food and Drug Administration; RDAs, Recommended Dietary Allowances; RDI, Reference Daily Intake; UL, upper intake level.

Based on Food and Nutrition Board. *Dietary Reference Intakes (DRIs): Recommended Intakes for Individuals.* Washington, DC: National Academy of Sciences; 2004, updated 2011[5]; Office of Nutrition Labeling and Dietary Supplements. *Food Labeling Guide.* College Park, MD: Food and Drug Administration; 2009.[6]

Most food labels are based on a “typical” diet of 2000 calories per day. However, the number of calories actually needed in a day depends on the individual’s daily expenditure of calories. Several formulae are available to calculate how many calories an individual needs daily,[7] but clinicians may not have the time to make those calculations. Another option is to use an Internet-based website that calculates the number of calories needed to maintain or lose weight when provided with the individual’s specific sex, age, height, weight, and daily activity levels (see the Resources section at the end of this chapter). According to guidelines issued by the American Heart Association, women age 19 to 30 years who are not obese and of average stature will need approximately 2000 calories per day to maintain their current weight if they do not engage in physical activity beyond activities of daily living such as work and walking to the bus (sedentary physical activity level). Women who are obese or very active will need more calories to maintain their current weight. Women who are older, or who are trying to lose weight, will require fewer calories. However, all food is not the same, and calories, therefore, are simply one consideration within a diet. The sections that follow review macronutrients, micronutrients, and the physiologic response to ingested food.

Macronutrients

Macronutrients contain calories and are the energy-providing nutrients for the human body. The three basic macronutrients are fat, carbohydrates, and proteins. Macronutrients are needed in large quantities and meet the bulk of a human body energy needs. One of the primary components of a healthy diet is consuming fat, carbohydrate, and protein in balanced proportions.

Fats

Fats are an important source of energy, providing more calories per gram than either protein or carbohydrates. Fat provides energy at a rate of 9 kcal/g, compared to 4 kcal/g for protein and carbohydrates. Fats are composed of fatty acids and have various roles in the human body, including transport and digestion of the fat-soluble vitamins and components of cell structure. Stored body fat facilitates temperature regulation by serving as insulation and helps to protect vital organs by providing a cushioning effect. In addition, dietary fat intake increases the pleasure of eating and helps signal satiety during a meal.

Since the 1950s, the American Heart Association has urged persons residing in the United States to eat less fat in their diets, particularly by eliminating cholesterol from red meat and eggs. This campaign has been successful in decreasing fat intake from 45% of total calories to 33%.[8] However, the percentage of calories consumed from fats is *not* linked to chronic diseases; instead, what matters is the *type* of fats consumed. The "fat is bad" campaign that caused people to replace fat calories with generally high glycemic (refined) carbohydrates has been shown to worsen serum lipoprotein levels and is one of the underlying causes of the current obesity and type 2 diabetes epidemic.[9]

Body Fats

Body fats need to be distinguished from dietary fat. For example, the cholesterol (a fatlike substance present in all animal tissue) consumed in diet is different than the cholesterol in blood that is measured as part of a lipid panel. Dietary cholesterol is found in foods of animal origin such as meat and eggs, while blood cholesterol is a waxy, fatlike substance manufactured by the body and stored in the liver. Fifty years of evidence has found that although there is a slight association between dietary cholesterol and serum cholesterol, dietary cholesterol has minimal effect on risk for cardiovascular disease due to the complexities of the metabolic effects of ingested food.[10] For example, eggs—a common source of cholesterol—also are rich in other nutrients that may counterbalance the cholesterol's detrimental effects on the cardiovascular system. In addition, more harmful physiologic effects may occur when an individual substitutes an egg for breakfast with a high-glycemic food, such as a large muffin, as discussed later in this chapter.

The body uses blood cholesterol to make steroid hormones such as estrogen and progesterone, as described in the *Anatomy and Physiology of the Female Reproductive System* chapter. Blood cholesterol is also required for production of vitamin D and bile, as well as being an important component of cell membranes.

Several subtypes of cholesterol are found in the body, although the two primary ones are low-density lipoprotein (LDL) and high-density lipoprotein (HDL). LDL transports cholesterol out of the liver to other parts of the body. Cells attach to these particles and extract LDL or cholesterol. Excess amounts of LDL promote the production of fatty plaques on arterial walls, causing them to lose elasticity and narrow, resulting in arteriosclerosis. If a plaque breaks free, it may cause a cardiac event such as a heart attack or stroke. LDL often is characterized as "bad" or "lousy" cholesterol. Conversely, HDL carries excess cholesterol away from the

arteries and back to the liver; thus, it is known as “good” or “healthy” cholesterol. A high level of HDL appears to have a protective effect against coronary heart disease and heart attacks. Exercise is strongly associated with higher levels of HDL in the body and, therefore, with lower risk of cardiovascular disease. In women, unlike in men, the total cholesterol to HDL ratio or the non-HDL level is more predictive of the risk for cardiovascular disease than the total cholesterol level.

The latest dietary guidelines recommend maintaining a daily dietary intake of cholesterol of less than 300 mg per day, and state that serum HDL level should be higher than 35 mg/dL, with a level of 60 mg/dL being optimal. The goal for the total cholesterol to HDL ratio is 5:1, with 3.5:1 being the ideal.

Another way in which fats are transported through the blood to cells is in the form of triglycerides. Serum triglycerides are derived either from consumed fat, especially trans fats, or synthesized de novo by body fat or the liver. The amount of triglycerides synthesized de novo is positively correlated with the consumption of refined carbohydrates. Triglycerides store excess calories as fat and break down stored fat when a source of energy is needed, especially by the brain. Whether a high triglyceride level is an independent cause of heart disease remains controversial, because many individuals with high triglyceride levels also have high LDL and low HDL cholesterol levels, which are known risk factors for heart disease.[11] It does appear, however, that high triglyceride levels are more predictive of cardiovascular disease risk in women than in men and are a risk factor for developing type 2 diabetes, metabolic syndrome, and ischemic stroke in women. Data collected for the National Health and Nutrition Examination Survey (NHANES) reveal that serum levels of total cholesterol, LDL, and triglycerides declined from the 1990s through 2014 in all population subgroups of women, even among those not taking lipid-lowering medications.[12]

Dietary Fats

Dietary fats are characterized by the chemical structure of their fatty acids. They are classified into four types: trans fats, saturated fats, polyunsaturated fats, and monounsaturated fats.

Trans Fats

Trans fats are produced when vegetable oils are heated in the presence of hydrogen gas and a catalyst, resulting in a partially hydrogenated oil. Such oils become a solid when they cool, making them easier to transport; they are more stable and unlikely to spoil, providing a longer shelf life; and they can be reheated without breaking down, so they are ideal for making fried foods. Although trans fats are found in small amounts in beef and dairy fat, they are largely consumed in the form of commercially made products. Trans fats are harmful because they elevate LDL cholesterol and lower HDL cholesterol; they also stimulate production of prostaglandins and other eicosanoids that increase inflammation, platelet aggregation, and vasoconstriction. The combination of these effects results in an increased risk for cardiovascular disease, diabetes, gallstones, weight gain, and ovulatory infertility.[13] The Nurses’ Health Study reported that for each 2% increase in calories from trans fats, the risk of

coronary heart disease increases 23%.[14] Evidence of adverse health effects following consumption of trans fats resulted in product labeling requirements that subsequently prompted the reformulation of many products to eliminate partially hydrogenated oils. Between 2003 and 2009, average trans fat intake decreased in the United States from 4.6 g/day to 1.3 g/day.[15]

Saturated Fats

Saturated fats are derived from both animal and plant sources. These fats often are solid at room temperature and are found in highest amounts in meat fat, butter, whole-milk products, coconut oil, palm oil, and palm kernel oil. Consumption of these fats worsens serum lipoprotein profiles.

Unsaturated Fats

In contrast to saturated fats, unsaturated fats have several beneficial roles in the body, including improving serum cholesterol levels, reducing inflammation, and stabilizing heart rhythms. These fats are found primarily in vegetable oils, nuts, and seeds, and are liquid at room temperature.

Unsaturated fats are of two types: *monounsaturated* and *polyunsaturated*. Monounsaturated fats are found in high concentrations in olives, peanuts, oils such as canola oil, avocados, nuts such as almonds and pecans, and seeds such as pumpkin and sunflower seeds. Polyunsaturated fats are grouped into two types, distinguished by their chemical bonds: omega-6 (n-6) and omega-3 (n-3) fatty acids. Both n-6 and n-3 are considered “essential fatty acids” due to the body’s limited ability to produce them, which means they must be obtained from dietary sources. Omega-6 fatty (linoleic) acids are found in safflower, sunflower, corn, soybean, and flaxseed oils, as well as canola oils. Omega-3 fatty acids are found in oily fish such as salmon, mackerel, anchovies, and sardines; algae; and plant sources such as chia and flax seeds, walnuts, and oils such as soybean and canola.

The amount of n-3 fats in the U.S. diet has decreased significantly since the 1950s, in part due to changes in the food chain. Today most meat comes from grain-fed animals; relatively speaking, grain-fed animals have less n-3 fats in their meat than grass-fed animals. The consumption of oily fish has also decreased over the same period of time, perhaps due to warnings about heavy metals in fish. Observational studies have shown that the incidence of heart disease mortality, stroke, and mood disorders appears to be correlated with differences in n-3 fat intake.[16] Results from supplementation trials with n-3 fats to prevent heart disease have been somewhat mixed, with some evidence suggesting that such supplements provide secondary prevention among those persons with heart disease, but have a limited effect in preventing arrhythmias.[17]

In summary, the total number of calories obtained from fat is unimportant for cardiovascular and general health; rather, it is the type of fats consumed that is important for health outcomes. Trans fats should be eliminated from the diet as much as possible. Replacing saturated fats with monounsaturated and polyunsaturated fats will provide modest improvements in protection against heart disease. Consumers should be cautious about the foods they choose to

substitute for trans fats and saturated fats, as some seemingly healthy alternatives are not necessarily healthier substitutes. Nevertheless, a good recommendation is to reduce consumption of red meat and whole-milk dairy products, increase intake of fish to at least two 6-ounce servings per week, and increase consumption of soy products, nonhydrogenated vegetable oils, and nuts. **Table 7-2** provides the distribution of daily recommended values of macronutrients for women age 19–30 years, and **Table 7-3** shows the recommended DRIs for women.[5,18]

Table 7-2 **Recommended Daily Values for Macronutrients for Women 19–30 Years**

	Percent Daily Calories (Actual Daily Amount)	
	Food and Drug Administration	**Health and Medicine Division**
Fat	30%	20–35%
Saturated fat	< 10%	As little as possible
Cholesterol	(< 300 mg)	As little as possible
Trans fat	0	0
Carbohydrates	60%	45–65%
Dietary fiber	(25 g)	(28 g)
Protein	10%	10–35%

Carbohydrates

Carbohydrates, which can be found in grains, vegetables, fruits, and sugars, are the major

dietary source of glucose, the body's essential energy for cellular metabolism. All carbohydrates except insoluble fibers are broken down by the body into the basic sugars and absorbed in the bloodstream. Glucose, galactose, and fructose can be used immediately by the body or can be stored in the liver or muscle tissue in the form of glycogen, which is then converted to glucose whenever there is a need for reserve energy.

In the past, carbohydrates have been described as simple or complex, with people being encouraged to eat more complex carbohydrates. However, there is no distinction in this recommendation between the different physiologic consequences that occur after eating different types of complex carbohydrates. Because the amount of insulin that is stimulated in response to carbohydrate intake is a key factor in the body's physiologic response, researchers have developed two measures to assess this response: the glycemic index and the glycemic load.[19] In general, ingestion of high-glycemic foods results in worsened lipoprotein profiles, more thrombotic activity, abnormal glucose metabolism, increased inflammation, and more cellular proliferation.

Glycemic Index

The glycemic index is a measure of the blood glucose response 2 hours after ingesting 50 grams of a food. This index is influenced by the amount of fiber and fat in the consumed food, both of which slow the absorption of the carbohydrate. Therefore, highly processed grains such as white bread, white rice, and semolina-flour pasta have a high index. For example, white rice's glycemic index is 89, whereas that for brown rice is 48. Vegetables have a low glycemic index due to their fiber content and low natural sugar content; indeed, in some cases, it is hard to even measure their glycemic index. For example, obtaining 50 grams of carbohydrate from broccoli requires ingesting 16 cups. Fruits, although naturally sweet, if consumed as the whole fruit, have a low glycemic index due to the fruit's fiber; for example, an apple has a glycemic index of about 10. In general, low-glycemic foods have a glycemic index less than 55, whereas those with a glycemic index higher than 70 are considered high-glycemic foods. The glycemic index values for a variety of foods have been published[16] and may be obtained online from the University of Sydney in Australia.

Glycemic Load

Compared to the glycemic index, the glycemic load is a better measure of the amount of insulin stimulated by consumption of specific foods. The glycemic load is calculated as the glycemic index of the food multiplied by the amount consumed, expressed per 100 grams. A low glycemic load is less than 10 and a high glycemic load is higher than 20, with values in between considered intermediate. For example, the glycemic index for one cup of brown rice is 45, but the glycemic load is 18. The same amount of white rice would have a glycemic index of 83 and a glycemic load of 43. This is a typical example, in which unprocessed grain products stimulate the production of less insulin than do processed foods such as white rice. The same is true for whole fruits as compared to consuming only the juice of the fruit. A person would need to consume 3 to 4 oranges to register the glycemic load of just 8 ounces of orange

juice.

Fiber

Fiber is a type of complex carbohydrate composed of nonstarch polysaccharides that cannot be digested by enzymes in the small intestine. Fiber is characterized as either soluble or insoluble based on its solubility in water. Soluble fiber types include pectin found in fruits, beta-glucans found in oats and barley, and gums found in beans and cereals. Insoluble fiber types include cellulose found in leaves, root vegetables (e.g., beets and carrots), bran, and whole wheat; hemicellulose found in bran and whole grains; and lignin found in plant stems and leaves. The typical U.S. diet is characterized by being low in dietary fiber. Fiber intake among adults in the United States averages approximately 16 grams, or only 60% of recommended amounts.[17] Research has revealed that dietary fiber is associated with a decreased risk of heart disease, most likely through lowering total cholesterol and LDL cholesterol levels, and with decreased risk of type 2 diabetes, diverticulitis, and constipation.

The Health and Medicine Division of the National Academies of Science, Engineering, and Medicine and the U.S. Department of Agriculture (USDA) recommend that carbohydrates compose 45% to 65% of daily caloric intake. Women should attempt to maximize their intake of low-glycemic foods rich in fiber, such as whole grains, vegetables, and fruits, and to minimize their intake of high-glycemic foods such as sweetened and energy drinks; refined grains such as white bread, white rice, and russet potatoes; and high-sugar snacks. A desirable intake of fiber for women is 20 to 28 grams per day.

Protein

Protein is the basic component of cells and is needed for cellular growth, replacement, and repair. Enzymes—the substances responsible for controlling the processes that keep the human body functioning smoothly—are composed of protein. Hormones, hemoglobin, and antibodies also are composed partially or entirely of protein. Protein, in turn, is composed of organic compounds known as amino acids. The different arrangements of amino acids into proteins determine the particular properties of each protein.

Approximately 20 amino acids exist that are necessary for human growth and metabolism. The body is able to produce the majority of these necessary amino acids. Approximately nine amino acids, however, must be obtained through foods—the so-called *essential amino acids*. Foods of animal origin, such as meat, poultry, fish, eggs, and dairy products, provide all of these essential amino acids and are known as complete proteins. Proteins derived from plants, such as legumes, nuts, and grains, lack certain essential amino acids and are termed incomplete proteins. Even so, a vegetarian diet can supply all of the essential amino acids as long as a variety of plant-based proteins are eaten throughout the day.[20]

Proteins cannot be stored in the body, so each day they must be consumed to avoid the body breaking down nonessential tissue, such as muscle, to supply proteins vital for survival. Recommended protein intake is 0.8 to 1.0 g/kg, or 10% to 35% of total calories. While protein intake deficiencies are common in the developing world, most persons in the United States

consume adequate amounts of protein. The average intake of women in the United States is approximately 70 g/day or 16% of kilocalories consumed, with only 8% of adolescents and older women having less than average intakes.[21]

The body does not distinguish between animal and plant sources of amino acids. However, protein food sources usually contain other nutrients, such as saturated fat. Evidence from the Nurses' Health Study suggests that substituting plant-based protein for high-glycemic carbohydrates can decrease a woman's risk for heart disease and type 2 diabetes.[22] **Table 7-4** contains a list of foods rich in complete and incomplete proteins.[23]

Table 7-4 Examples of Food Sources of Protein

Food	Quantity	Amount of Protein (g)
Complete Proteins		
Beef, chuck roasted	3 oz	26
Chicken, roasted	3 oz	27
Tuna, fresh	3 oz	25
Pork, center loin	3 oz	23
Beef, lean ground	3 oz	22
Tuna, canned	3 oz	20
Ham	3 oz	19
Chicken breast, deli-type slices	3 oz	17
Salmon	3 oz	17
Scallops	3 oz	17
Cottage cheese	½ cup	14
Eggs	2 large	13
Shrimp	3 oz	12
Yogurt	1 cup	8–12
Milk, any type	1 cup	8
Cheddar cheese	1 oz	7
Incomplete Proteins		
Lentils	1 cup, cooked	18
Beans, cooked (different types)	1 cup	12–15
Tofu, firm	½ cup	10
Green peas	1 cup	9
Quinoa, cooked	1 cup	8
Peanut butter	2 Tbsp	8
Peanuts	1 oz	7
Egg noodles, cooked	1 cup	7
Brown rice, cooked	1 cup	5
White rice, cooked	1 cup	4
Bread, whole wheat	1 slice	4

Sunflower seeds	1 oz	4

Physiologic Response to Food Intake

Food is a hormonal stimulant more powerful than most drugs. Understanding this reality may be the impetus providers need to spend time with women assessing their diets and helping them to choose better foods. The body's response to food intake depends on the composition of both the macronutrients and the micronutrients ingested. With regard to prevention of inflammation and other processes that promote disease, especially chronic disease, the most important physiologic response to food intake is how much insulin production is stimulated. Stimulation of insulin production is a direct response to the amount and rate of glucose response from a meal. This glucose response can be measured by estimating the glycemic index of a meal.

Distinguishing high-glycemic meals from low-glycemic meals is important in understanding the body's physiologic response.[19] A high-glycemic meal creates a rapidly rising and high blood glucose response, which results in a similar insulin production response. Subsequently, the blood glucose level falls more rapidly than the insulin level decreases, which results in high insulin levels, low glucose levels, and suppression of glucagon production. Faced with these conditions, the body responds as if there is adequate glucose—that is, it suppresses the secretion of free fatty acids, blocking the body's access to stored fat for energy. Low glucose levels also cause poor brain function, which stimulates the appetite, especially for a high-glycemic meal. After several more hours, to maintain a euglycemic state, skeletal muscles become insulin resistant, decreasing glucose uptake. In turn, free fatty acids and cortisol are secreted to allow access to stored glucose from the liver. In addition, other inflammatory hormones are released, causing oxidative stress and potentially damage from the production of excessive free radicals. Over time, this cycle of increased levels of glucose, insulin, and free fatty acids damages pancreatic beta cells, potentially resulting in type 2 diabetes, as well as affecting other processes associated with a variety of conditions, including cardiovascular disease, cancer, neural tube defects in the fetus (if the woman is pregnant), and gallbladder disease.

Eating a diet rich in carbohydrates from whole grains, beans, fruits, and vegetables results in a much more modulated glucose response, in which insulin levels follow but never exceed glucose levels. Therefore, the result is appropriate glucagon stimulation. Over time, as glucose levels decline, stored fat then is available as an alternative energy source until the next meal.

The metabolism of fatty acids results in another important set of physiologic responses. This metabolism leads to the formation of different types of eicosanoids. Eicosanoids are short-acting, powerful, locally acting hormones that aid intracellular communication and regulate cyclic adenosine monophosphate (cAMP), which is needed for peptide hormones to exert their effects in cells. The first-identified eicosanoid was prostaglandin, but midwives will recognize other eicosanoids such as prostaglandin E_2, prostaglandin F_2-alpha, and thromboxane, which exist endogenously. These specific agents can dampen cAMP activity as well as exert a pro-inflammatory effect, increase platelet aggregation and cellular proliferation, and cause vasoconstriction. Conversely, the hormones that increase cAMP (e.g., prostacyclin, PGE_1) have the opposite effects. The body needs all of these substances for self-regulation and appropriate functioning. With regard to nutrition, the type of eicosanoid produced, either pro-inflammatory or anti-inflammatory, is influenced by such factors as the

presence of insulin, glucagon, omega-3 fatty acids, and trans fats. In brief, the quality of human nutrition encompasses not only the type of food that is consumed, but also the physiologic and chemical responses to it, as well as the presence of viruses and stress.

Micronutrients: Vitamins and Minerals

Micronutrients are dietary elements that the body needs in trace amounts. Metabolism and use of macronutrients by the body require a host of enzymatic and hormonal processes that are also influenced by the necessary presence of micronutrients—specifically, vitamins and minerals, which for the most part cannot be synthesized by the body. Micronutrient deficiencies can have profound adverse health effects. Micronutrient deficiencies are a common health problem in developing nations and in some geographic areas in developed nations.

Vitamins are organic substances used by the body as catalysts for intracellular metabolic reactions, whereas minerals are inorganic substances. Both vitamins and minerals are essential for physiologic function, but must be obtained via the diet. Vitamins are classified as fat-soluble or water-soluble: Water-soluble vitamins are excreted from the body and are not stored, whereas fat-soluble vitamins are stored in body fat.

A few of these micronutrients are highlighted here because they play a special role in women's health or because women in the United States are likely to be deficient in them. The role of vitamins and minerals in pregnancy are discussed in the *Prenatal Care* chapter. **Table 7-5** lists the recommended intakes for selected vitamins and minerals in women age 14 to 70 years, the requirements in pregnancy and lactation, and common food sources of these nutrients.[24]

Table 7-5 **Recommended Daily Reference Intakes of Vitamins and Micronutrients in Women**

Vitamin/Mineral	Nonpregnant Women 14–18 Years	Nonpregnant Women 19–50 Years	Nonpregnant Women 51–70 Years	Pregnancy	Lactation	Dietary Source
Vitamin A (mcg)	700	700	700	770	1200	Yellow/orange vegetables and fruits
Vitamin C (mg)	65	75	75	85	120	Citrus fruits
Vitamin D (IU)	600	600	600	600–4000[a]	600–4000[a]	Fortified dairy
Vitamin E (mg)	15	15	15	15	19	Nuts, vegetable oils
Thiamin (mg)	1.1	1.1	1.1	1.4	1.4	Pork, enriched grain
Riboflavin (mg)	1.1	1.1	1.1	1.4	1.4	Meat, enriched grain
Niacin (mg)	14	14	14	18	17	Meat, nuts, legumes
Vitamin B_6 (mg)	1.2	1.3	1.5	1.9	2.0	Chicken, fish, enriched grains
Folate (mcg)	400	400	400	600	500	Leafy vegetables, liver, fortified cereal
Vitamin B_{12} (mcg)	2.4	2.4	2.4	2.6	2.8	Animal-based food
Calcium (mg)	1300	1000	1200	1300	1300	Dairy
Magnesium (mg)	360	320	320	350–360	310–320	Seafood, legumes, grains
Phosphorus (mg)	1250	700	700	700	700	Meat
Potassium (g)	4.4	4.7	4.7	4.7	5.1	Apricots, figs, nuts, soy, wheat germ
Iodine (mcg)	150	150	150	220	290	Iodized salt, seafood
Iron (mg)	15	18	8	27	9	Meat, eggs
Choline (mg)	400	425	425	450	550	Eggs
Zinc (mg)	9	8	8	11	12	Egg yolk, liver, oysters

Fat-Soluble Vitamins

Large doses of fat-soluble vitamins are stored in the body and can reach toxic levels that have dangerous effects. For example, accumulation of vitamin A, which occurs when this nutrient is ingested as retinol, can result in liver toxicity, visual problems, and increased risk for hip fractures.

Vitamin A is important for vision (especially night vision), a healthy immune system, and cell growth. Vitamin A deficiency is rare in the U.S. population, but it may be an important nutrient to attend to in low-resource countries. **Table 7-6** presents the current status of micronutrients in childbearing women in the United States.[25,26]

Table 7-6 Recommended and Actual Status of Micronutrients in U.S. Women 20–39 Years of Age by Race/Ethnicity According to National Nutrition and Health Examination Survey, 2003–2006

		Actual Status for Women 20–39 Years of Age, Geometric Mean Values			
Micronutrient (Measurement)	Adequate Levels in Women	All Women 20–39 Years	Mexican	Non-Hispanic Black	Non-Hispanic White
Vitamin A (mcg/dL)	> 20	50.0	45.0	42.7	53.5
Vitamin B_{12} (pg/mL)	> 400	439	501	489	414
Vitamin D 25(OH)D (nmol/L)	≥ 50 or 75	55.3	43.9	32.7	66.7
Vitamin E (mcg/dL)	> 500	1010	1000	917	1040
Folate as RBC folate (ng/mL)	> 95[a] > 330[b]	253	256	213	267
Iron as serum ferritin (ng/mL)	> 15	38.1	33.7	30.1	41.0
Iodine: urinary excretion (ng/L)	100–199	118	171	118	112
Iodine: during pregnancy[c]	150–249	129[d]			

Abbreviation: RBC, red blood cell.

[a] Amount to prevent hypersegmented RBCs.

[b] Amount to prevent neural tube defects.

[c] Years 2005–2010 (Caldwell).

[d] Below adequate levels.

Data from National Center for Environmental Health. *Second National Report on Biochemical Indicators of Diet and Nutrition in the U.S. Population*. Atlanta, GA: Centers for Disease Control and Prevention; 2012[25]; Caldwell KL, Pan Y, Mortensen ME, Makhmudov A, Merrill L, Moye J. Iodine status in pregnant women in the National Children's Study and in U.S. women (15–44 years), National Health and Nutrition Examination Survey 2005–2010. *Thyroid.* 2013;23(8):927-937.[26]

Vitamin D promotes absorption of calcium and phosphate and helps deposit these minerals in teeth and bones, but also plays a role in health beyond bone formation. Most body tissues have vitamin D receptors; thus, this vitamin is involved with regulation of many systems, such as blood pressure, glucose and insulin regulation, and modulation of the immune system. Vitamin D is a not a true vitamin, as humans synthesize D_3 when the skin is exposed to ultraviolet sunlight. Vitamin D_3 synthesis from sunlight is affected by intensity of sunlight,

especially related to latitude and season; the presence of air pollution; and factors that limit the skin's absorptive ability, such as amount of pigmentation, presence of sunscreens, and increasing age. Oily fish and fish liver oils are other sources of vitamin D_3, although absorption is decreased in people with intestinal malabsorptive conditions. Vitamin D_2—another form of vitamin D—is derived from plant sterols, such as those found in mushrooms. Vitamin D is also consumed through fortified dairy products. Both D_3 and D_2 are inactive forms that require metabolism in the liver to convert the vitamin D to 25(OH)D, the form most commonly used to assess a person's vitamin D levels, followed by metabolism in the kidney to convert it to $1,25(OH)_2D$, the physiologic active form.

Vitamin D deficiency has historically been defined as a serum 25(OH)D concentration less than 10 ng/mL (25 nmol/L), which is the level at which rickets or myopathy develops. Currently, there is some controversy about what constitutes vitamin D deficiency in adults based on whether the goal is bone health only or if other general health conditions are also considered. The Health and Medicine Division's Food and Nutrition Board, using bone health as the goal, has defined a vitamin D level of less than 50 nmol/L (20 ng/mL) as inadequate, with the recommended range for this vitamin being 50–100 nmol/L (20–40 ng/mL).[27] This agency recommends supplement intakes of 600–800 IU in the absence of adequate sunlight, with an upper tolerable limit of 4000 IU. However, the U.S. Endocrine Society, the American Geriatrics Society, and Central Europe guidelines recommend a minimum of 75 nmol/L (30 ng/mL) as the vitamin D level, with a level in the range of 75–155 nmol/L (40–60 ng/mL) considered ideal.[28,29] These organizations acknowledge that individuals may need to consume 1500–2000 IU daily to achieve these levels, with an upper tolerable level of 10,000–40,000 IU. Adults who are obese or who take anticonvulsants, glucocorticoids, some antifungals, or antiretroviral drugs, or who have inflammatory bowel disease or gastric bypass surgery, may require two to three times this dose to achieve healthy levels.[28]

Despite the current controversy about precisely which serum values represent vitamin D deficiency—vitamin D 25(OH)D levels of less than 20 ng/mL (50 nmol) versus less than 30 ng/mL (75 nmol)—there is no question that vitamin D deficiency is prevalent in all ethnic groups of women in the United States (**Table 7-6**). More than 50% of women in the United States have serum vitamin D levels less than 50 nmol/L (20 ng/mL), and non-Hispanic black women and Mexican women have particularly low average levels.[25]

Water-Soluble Vitamins

Folic Acid

Among the water-soluble B vitamins, folic acid (vitamin B_9) has a great import for childbearing women due its role in preventing neural tube defects. Folate is essential for RNA and DNA synthesis. Observational studies have found high folate levels to be associated with lower rates of cancer (especially intestinal cancer), cardiovascular disease, dementia, and depression. Supplementation with folate and other B vitamins has proved effective in lowering homocysteine levels, which are associated with cardiovascular disease. However, randomized trials of fairly large populations have not found that vitamin B supplements decrease the incidence of any of these conditions. Nevertheless, folate deficiency is clearly associated with megaloblastic anemia. Women at risk for megaloblastic anemia include those with poor diets, alcoholics, and those who have malabsorptive disorders or take pharmaceutical agents that act as folic acid antagonists (e.g., anticonvulsants, sulfasalazine [Azulfidine]).

Folate is found in liver and leafy greens such as spinach, but the primary dietary source of this micronutrient in the United States is fortified cereal and multivitamin supplements. Folate status can be assessed by either serum folate or red blood cell (RBC) folate tests, although the latter is a better indicator of tissue levels or long-term status.

In general, the U.S. population is not folate deficient. Since food fortification began in the mid-1990s, the percentage of the population that is folate deficient, defined as being at risk for hypersegmented RBCs, in all age and ethnic groups is 1% or less.[30] Discussion about adequate levels for pregnancy can be found in the *Prenatal Care* chapter. Although there is little risk of toxicity from high folic acid intake, concern has arisen that consumption of excess amounts could exacerbate the anemia and cognitive symptoms associated with vitamin B_{12} deficiency. Therefore, folic acid supplements of 1 mg or more require a provider prescription.

Vitamin B_{12}

Vitamin B_{12} deficiency can lead to anemia, and neurologic and cognitive dysfunction including depresson.[31,32] Everyone needs vitamin B_{12} in their diet; human beings do not make this vitamin on their own, and the vitamin B_{12} that may be produced by bacteria in the colon is mostly not bioavailable. Subgroups at risk for vitamin B_{12} deficiency are those with small bowel or inflammatory bowel disease, history of gastric bypass surgery, vegetarians, and elderly persons. If a pregnant woman is vitamin B_{12} deficient, she should be quickly treated, since this condition may affect the developing fetus.

Beef liver, beef, fatty fish (e.g., salmon), and dairy products are good dietary sources of vitamin B_{12}. For vegetarians, this nutrient may be obtained from soy and other products like nutritional yeast, which is fortified with vitamin B_{12}.

Recommended routine supplementation of vitamin B_{12} and eating vitamin B_{12}–fortified foods is recommended by the Food and Nutrition Board for all adults older than age 50 due to the prevalence of atrophic gastritis in older adults, which inhibits absorption of vitamin B_{12}.[33]

A 2015 meta-analysis of the use of vitamin B_{12} supplements in conjunction with antidepressants among individuals with depression did not show any short-term benefit from this adjunct therapy, but supplementation may be useful in preventing depression relapse.[31]

Vitamin B_{12} supplements may be provided as injections, orally or intranasally. Oral supplements are relatively inexpensive and widely available. The most common form of vitamin B_{12} supplement—and the best studied—is cyanocobalamin. A typical vitamin B_{12} supplementation regimen might be 250–500 mcg/day, which would probably compensate for poor absorption of supplements. However, smokers should be aware that vitamin B_{12} supplementation with cyanocobalamin may not be effective for them; smokers may excrete much more cyanocobalamin in the urine.[32] Research on this topic is far from definitive, but smokers might consider a non-cyanocobalamin form of vitamin B_{12}, such as methylcobalamin. Although some sources suggest that sublingual doses are more readily absorbed, the only study comparing routes found no difference in efficacy between sublingual and oral ingestion of vitamin B_{12}.[33] Intake of relatively high doses of vitamin B_{12} does not appear to be associated with any detrimental health problems, so no upper tolerable limit has been established.[34]

In summary, most women in the United States have adequate intakes of vitamins, with the exception of vitamin D and, in some subpopulations, folate or vitamin B_{12} (e.g., in the elderly). Nutrition scientists have been learning more about the roles that vitamins play in health beyond the basic understanding achieved in the twentieth century. Randomized trials on the use of vitamin supplements as a means to prevent chronic disease have yielded disappointing results, but it may be that, without addressing the content of the entire diet, vitamin supplementation is not powerful enough to overcome the physiologic effects of types and amounts of macronutrients in the diet.

Minerals

Minerals are chemical compounds found in the earth and absorbed by plants or animals, or dissolved in water. The five major minerals found in the human body are calcium, magnesium, phosphorus, potassium, and sodium. The other minerals needed in minute quantities, called “trace minerals,” have specific functions within the body; they include cobalt, copper, iodine, iron, manganese, molybdenum, and selenium. The minerals reviewed in this chapter are those that are most commonly associated with deficiencies and their resulting adverse health conditions.

Calcium

Calcium is essential not only for healthy bone and teeth formation, but also for nerve conduction, muscle contraction, and blood clotting. Because more than 30% of women in the United States older than 50 years are at risk for bone fracture due to osteoporosis,[35] maximizing peak bone mass through adolescence and early adulthood is essential. Unfortunately, adolescent girls have the lowest total intakes of calcium, 918 mg ± 30 mg per day, with only 13% to 15% meeting the daily requirement of 1300 mg from both diet and supplements.[36] In addition to calcium’s role in building bone mass during adolescence and early adulthood, it is important that women obtain adequate amounts of calcium throughout the lifespan to maintain bone mass. Many older women meet their calcium needs by taking a daily supplement or calcium carbonate antacids. **Table 7-7** lists common food sources of calcium.

Table 7-7 **Examples of Sources of Calcium**

	Serving Size	Calcium (mg)		Serving Size	Calcium (mg)
Dairy			**Fruits and Vegetables**		
Yogurt, fruit variety, nonfat	8 oz	345	Orange juice, calcium fortified	6 oz	200
Milk, calcium fortified	8 oz	400	Orange, navel	1	52
Milk, 1%	8 oz.	300	Raisins, seedless	2 oz	28
Lactaid milk	8 oz	300	Broccoli, steamed	½ cup	31
Cheese, American	1 oz	174	Collards, fresh cooked	1 cup	268
Cheese, cheddar	1 oz	204	Collards, frozen, boiled	½ cup	179
Cheese, mozzarella	1 oz	222	Spinach, fresh	1 cup	245
Cottage cheese, nonfat	8 oz	125	Spinach, chopped frozen	½ cup	145
Ice cream	8 oz	176	Kale, fresh, cooked	1 cup	94
Milk, nonfat dry powder	2 Tbsp	104	Mustard greens, fresh	1 cup	165
			Rhubarb, fresh diced	1 cup	105
			Blackstrap molasses	2 tsp	118
Seafood			**Nuts, Seeds, and Beans**		
Clams, canned	3 oz	78	Almonds	1 oz	76
Salmon, pink, canned	3 oz	240	Tahini (sesame paste)	1 Tbsp	64
Sardines, canned in oil	2 oz	216	Beans, white, canned	1 cup	191
Ocean perch	3 oz	29	Beans, navy, canned	1 cup	123
Halibut, baked	3 oz	51			
Shrimp (shelled)	3 oz	60			
Soy Products			**Cereal**		
Tofu, firm prepared with calcium sulfate	4 oz	253	Oatmeal, instant	1 packet	105
			All Bran (Kellogg)	½ cup	121
Tofu, soft	4 oz	150	Cheerios (General Mills)	1 cup	112
Soy milk	8 oz	300	Total (General Mills)	¾ cup	1000
			Tortilla, corn, 6 in.	1	45
			Bread, whole wheat	1 slice	30
Antacids					
Tums, regular	1	200			
Tums, extra strength	1	300

Iodine

Iodine is essential for normal thyroid function, and deficiency of this mineral can lead to an enlargement of the thyroid gland known as goiter. Dietary iodine is obtained primarily from iodized salt, fish, and seaweed. From the late 1970s to 2000, iodine levels in the U.S. population declined by 50%, though levels have since stabilized.[26] This decline is probably due to a combination of decreased intake of salt, fish, and possibly dairy products, which

collectively account for 60% of iodine intake. The currently popular exotic salts, such as Fleur de Sel and pink salt, are not iodized. The recommended daily intake of iodine is 150 mcg, which would result in a urinary iodine level of 100 mcg/L. The most recent data show that, in general, the U.S. population obtains sufficient iodine, but 37% of childbearing-age women have urinary iodine levels below this threshold, with the highest proportion of such deficiency occurring among non-Hispanic blacks.[26]

Iron

The most common nutritional deficiency globally is iron deficiency, which disproportionally affects women. Iron is essential to the production of hemoglobin and, therefore, for the transport of oxygen. Red blood cells contain 80% of the body's iron, where it can be measured as hemoglobin. Iron not in red blood cells is stored as ferritin; transferrin is a protein needed for this stored iron to be transported in the circulation. Women who are not pregnant are at risk of anemia because of iron loss during menstruation, coupled with inadequate iron intake or decreased iron stores associated with close spacing of pregnancies. Special populations of women at higher risk for iron-deficiency anemia include pregnant women and those with malabsorption, such as women with inflammatory bowel disease and women who have undergone bariatric surgery. Slightly less than 1 mg of iron is lost from the intestines daily; this daily iron loss is more than 1 mg among women with *Helicobacter pylori* infection, malaria, or infection with intestinal parasites.

Two forms of iron are found in food: heme and non-heme. Heme iron found in animal products is absorbed more efficiently than non-heme iron. For example, 20% to 30% of heme iron is absorbed, compared to 2% to 10% of non-heme iron. **Table 7-8** lists some common dietary sources of iron. Iron uptake also varies according to the specific needs of a woman's body. If a woman has adequate iron stores, only approximately 10% of ingested iron is absorbed. In the presence of iron deficiency, however, as much as 40% of ingested iron can be absorbed.

Table 7-8 **Examples of Dietary Sources of Iron**

Source	Serving Size	Iron (mg)
Breakfast cereals: varies by brand	1 cup	5–18
Prune juice	1 cup	10
Chicken liver	3 oz	8
Beef liver	3 oz	7
Cream of wheat	½ cup	7
Oysters	6	6
Sunflower seed kernels	2 oz	4
Prunes	10	4
Beans: lentils, kidney, garbanzo	2.3 cup	2–3
Beef	3 oz	3
Pork	3 oz	2

Sesame seeds	2 oz	2
Leafy green vegetables, cooked	1 cup	2
Molasses, blackstrap	1 Tbsp	2
Tortilla, wheat/corn, 6 in.	1	1.8/0.7
Chicken	3 oz	1
Plantains, cooked	1 cup	1
Peanut butter	2 Tbsp	0.6

Accessed May 11, 2017.[23]

Some foods or supplements can enhance or inhibit iron absorption, and these items should be discussed when counseling women. Iron uptake enhancers include animal muscle from meat, chicken, or seafood; foods containing vitamin C and, in populations deficient in vitamin A, vitamin A; and fermented vegetables and sauces (e.g., sauerkraut, kimchee, and soy sauce). Iron uptake inhibitors include foods containing phytates (e.g., whole grains, oats, bran, nuts, spinach), phenols (e.g., tea, especially green tea; coffee; cocoa; and red wine), calcium, and soy proteins. Iron absorption also is decreased in the presence of antacids. *Pica*—a condition characterized by persistent and compulsive eating of non-nutritive substances, including excessive consumption of ice—can be either a symptom of anemia or a contributing cause. Frequently, the correction of the anemia will eliminate the pica.

The loss of iron stores is followed by anemia. Adequacy of iron stores can be measured in several ways. The most commonly available tests assess characteristics of the red blood cells, such as hemoglobin level, and perform a peripheral smear to characterize the morphology of the RBCs. However, biochemical tests of serum ferritin and transferrin saturation measure earlier stages of iron depletion prior to actual iron deficiency as evidenced by a low hemoglobin level. The primary laboratory and clinical findings with differing states of anemia are discussed in the *Common Conditions in Primary Care* and *Pregnancy-Related Conditions* chapters. Although iron-deficiency anemia typically is associated with pale (hypochromic) and small (microcytic) RBCs, changes in RBC morphology occur relatively late in the process.

According to NHANES data, the overall prevalence of iron-deficiency anemia in women who reside in the United States is 11% among nonpregnant women and twice that rate among pregnant women. However, this estimate is based on measures of iron stores, such as serum ferritin or transferrin saturation. If hemoglobin level (the most widely available measurement method) is used to assess for iron-deficiency anemia, the incidence is lower, approximately 6%.[37] Differences in the use of vitamin supplements by race/ethnicity appear to account for the increased prevalence of anemia among blacks and Hispanics. Approximately 10% to 13% of older women have been found to have anemia, with elderly black women having at least twice the rate of elderly white women.[38]

Women diagnosed with iron-deficiency anemia who increase their dietary consumption of iron-rich foods and avoid taking antacids 2 hours before or 4 hours after meals may correct the problem nutritionally. The other option for remedying this deficiency is iron supplementation.

After the addition of 30 mg to 100 mg of elemental iron taken daily, an increase in the reticulocyte count should be noted within 2 weeks and an increase in the hemoglobin noted within 3 to 4 weeks.

Ferrous salts are the first-line choice for oral iron supplementation for the treatment of women with iron-deficiency anemia. Other types of iron supplements are not more effective, do not appear to have a more benign side-effect profile, and cost approximately four times as much as ferrous salts. Because a maximum amount of absorption is possible at one time, divided doses are preferable. Also, separating administration of iron from ingestion of a multivitamin can maximize absorption.

Side effects of iron therapy, such as nausea, bloating, abdominal cramping, and constipation, are proportional to the dose. Frequently women will discontinue therapy due to these side effects. Women should be counseled about the potential side effects and measures they can take to lessen them. An alternative to daily iron supplementation is taking 120 mg of elemental iron once or twice weekly. It is not recommended that women double their multivitamin supplement in an effort to obtain added iron, as this approach could result in excessive levels of fat-soluble vitamins.

Table 7-9 lists types of iron supplements and the amounts of elemental iron in each dose. Enteric-coated and slow-release iron formulations are not recommended because iron is absorbed in the small intestine and these products provide iron that is excreted unabsorbed. A key safety issue is that iron supplements—particularly those prescribed prenatally—are one of the leading causes of childhood poisoning.[39] All women should be cautioned to keep their medications out of the reach of children.

Table 7-9 Iron Supplements

Iron (Fe) Group	Generic Name (Brand)	Dose Elemental Iron (mg)
Iron Salts		
Tablets	Iron sulfate (FeoSol)	325 (60)
	Iron fumarate (Feostat, Hemocyte)	200 (66)
	Iron gluconate (Fergon)	300 (35)
Liquid	Iron sulfate elixir (FeoSol Elixir)	22 (44) per 5 mL 300 (60) per 5 mL
	Iron gluconate + herbs (Floradix or Floravital—gluten free)	(10) per 10 mL—higher absorption rate
Polysaccharide Iron/Carbonyl Iron		
Tablets	Carbonyl iron (FeoSol caplets)	50 (45)
	Polysaccharide iron (Ferrex-150)	150 (150)
Liquid	Polysaccaride-iron elixir (Niferex Elixir)	100 (100) per 5 mL

Role of Vitamin and Mineral Supplementation

Ideally, micronutrients should be obtained through intake of a variety of fruits and vegetables each day—at a minimum, five servings per day—and exposure to adequate sunlight. Unfortunately, fewer than one in four individuals in the United States meets the daily fruit recommendation and only 13% meet the recommendation for daily intake of vegetables.[40]

Use of supplements is not a substitute for a healthy diet. While noting that there is little harm in taking a daily multivitamin supplement, the U.S. Preventive Services Task Force (USPSTF) does not currently recommend routine multivitamin/mineral supplementation for the general population for the prevention of chronic diseases such as cardiovascular disease. However, this recommendation does not apply to populations at risk for deficiencies, including women who have undergone gastric bypass and those who have malabsorptive conditions or take medications that can result in lower absorption. As discussed in the section "Dietary Patterns," limited supplementation should be at least considered by vegetarians, and especially by vegans. However, consumption, by anyone, of large doses of iron and of vitamin supplements, particularly fat-soluble vitamins, can potentially be hazardous.

Although studies of multivitamin supplements have not shown a benefit in preventing chronic disease, several expert panels have highlighted the deficiencies in these studies. First, these studies use a non-uniform definition of a "multivitamin"—that is, differences in the number of vitamins included and the presence or absence of specific minerals. Second, most studies have been cross-sectional and relied solely on self-reports, which may be not be accurate—especially when recalling intake many years in the past.

The longitudinal Physicians Health Study did find multivitamin use was associated with a decrease in epithelial cancer and cataracts.[41] A recent systematic review concluded that, at the very least, multivitamin/mineral supplements do not seem to cause any harm.[42] Therefore, in general, taking a multivitamin/mineral supplement "just in case" seems to do no harm although it may not be money well spent.

Dietary Patterns

When discussing nutrition, a healthcare provider will probably be of most value to a woman by emphasizing healthier dietary patterns that are relevant at any weight and are applicable throughout her life course. The word “diet” is often interpreted by many laypersons too narrowly—that is, as meaning “a weight-loss diet.” It may be helpful, therefore, to use a less-familiar term such as “dietary pattern” with a woman when counseling her on nutrition. The USDA highlights three food patterns that are recommended as healthy dietary patterns: (1) the United States 2010 Dietary Guidelines, which are similar to the Healthy Eating Pyramid; (2) the Mediterranean-style eating pattern; and (3) the healthy vegetarian eating pattern.

Healthy Eating Pyramid and Healthy Eating Plate

The Healthy Eating Pyramid was developed by faculty in the Department of Nutrition at Harvard School of Public Health and adopted by the United States Department of Agriculture (USDA) in 1991.[43] The pyramid is a graphic that illustrated recommended quantities of food intake per day in different food categories.[43] The bottom of the pyramid and bulk of one’s diet is made of vegetables, fruits, health fats and oils, and whole grains. The top of the pyramid are those foods eaten sparingly such as red meat, butter, processed meat, refined grains, sugary drinks, and salt.[43]

In 2011, the USDA replaced the Healthy Eating Pyramid with The Healthy Eating Plate graphic (**Figure 7-1**).[45] The USDA Healthy Eating Plate graphic has the advantage of being a simple illustration but it does not convey important diet choices recommended by the Harvard researchers who created the pyramid (e.g., whole grains are better than any grains). Nonetheless, the USDA Healthy Eating Plate is an easy teaching tool that can be used with the Healthy Eating Pyramid and key principles outlined in **Table 7-10** in discussions about recommended dietary patterns.[8,43-45] The Resources section at the end of this chapter has links to the Harvard versions of the Healthy Eating Pyramid and Healthy Eating Plate for more detail about their use in clinical practice. Essentially, women can see that half their plate should be occupied by vegetables and fruits (minimum of 5 servings per day), one-quarter with whole grains, and one-quarter with protein, with the addition of a healthy unsaturated fat. It is also important to discuss fluid intake, especially if it is a source of high-glycemic, high-calorie intake, such as the empty calories found in sugared beverages.

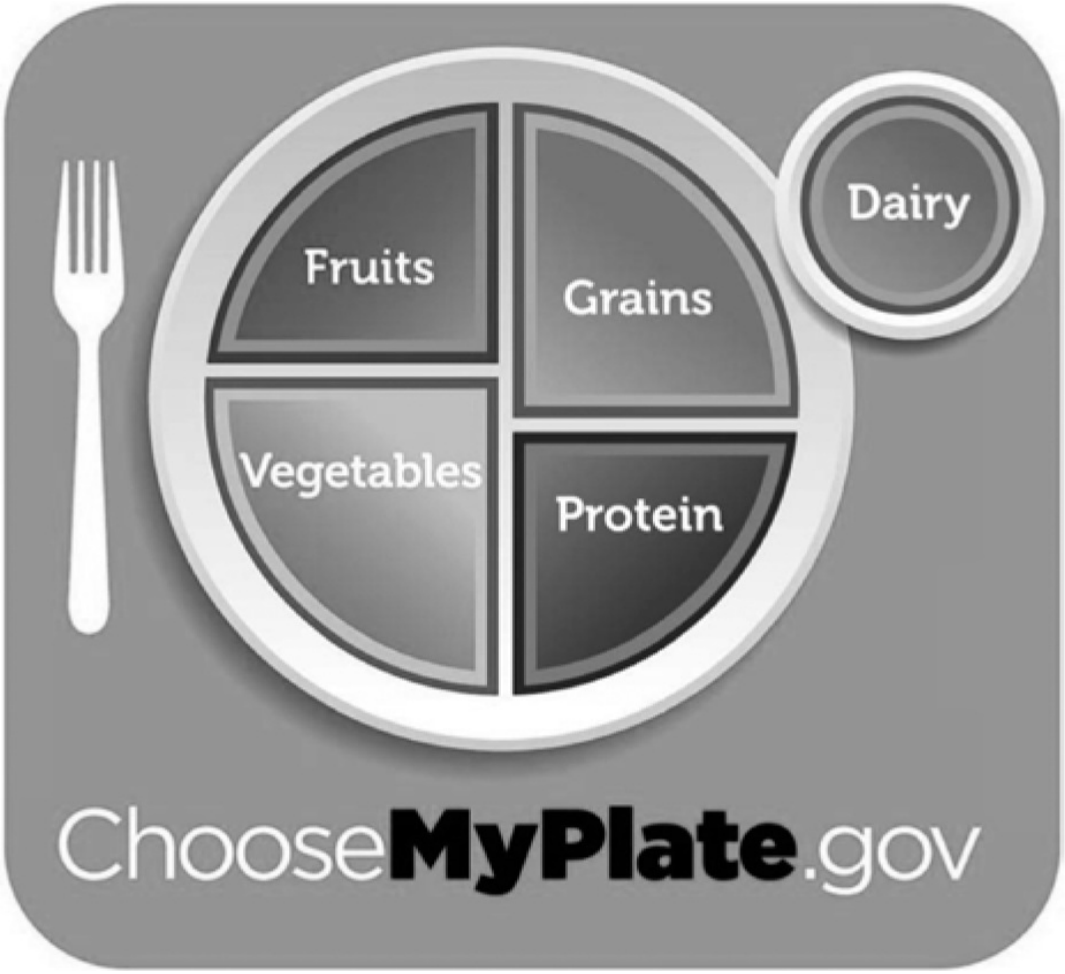

Figure 7-1 The Healthy Eating Plate.

Table 7-10 **Key Principles in the Healthy Eating Pyramid**

1. Choose healthy fats instead of unhealthy fats.
   - Avoid trans fats; choose monounsaturated and polyunsaturated fats.
2. Choose slowly digested carbohydrates over highly refined ones.
   - Emphasize whole fruits, vegetables, beans, and nuts.
   - Choose whole grains, such as brown rice, bulgur, barley, quinoa, and wheat berries.
3. Choose proteins that are plant based at least half of the time, and choose fish, eggs, and poultry the rest of the time, eating little red meat.
4. Eat large amounts of fruits and vegetables—a minimum of 5 servings per day.
5. Choose low-calorie hydration—water is best.
   - Drink coffee and tea in moderation.
   - If milk is part of the diet, choose low-fat types.
   - Limit juice to one small glass per day.
   - Avoid high-sugar drinks.

- Limit alcohol intake to one glass per day.

6. Meet daily recommendations for vitamins and minerals.
7. Get daily exercise—30 minutes of brisk walking daily.
   - Calories expended are important to maintain a healthy weight.

The dietary pattern promoted in the Healthy Eating Pyramid and Healthy Eating Plate is similar to two other dietary patterns that have been associated with decreases in chronic diseases, especially cardiovascular disease: the Mediterranean diet and the DASH (Dietary Approaches to Stop Hypertension) diet.

Mediterranean Diet

The Mediterranean diet emphasizes eating primarily vegetables, grains, beans, nuts, and seeds, with a serving of fish, poultry, or egg, and small amounts of cheese or yogurt, and obtaining 40% of calories from fats, primarily olive oil.[46] Similarly, the DASH diet emphasizes 8 to 10 servings of fruits and vegetables per day and choosing low-fat/nonfat protein sources; it also limits salt consumption and limits fats to 27% of calories. The DASH diet places less emphasis on the type of fat, except to limit saturated fat to less than 7% of calories. A variant of the DASH diet is the OmniHeart (Optimal Macronutrient Intake Trial to Prevent Heart Disease) diet, which somewhat reduces carbohydrate intake relative to the DASH diet, compensating for the caloric loss by substituting either protein or unsaturated fat. The investigators who studied the OmniHeart diet documented further lowering of blood pressure, further improved lipid levels, and further reduced cardiovascular risk compared to the already-healthier standard DASH diet.[47] Finally, the "portfolio" dietary pattern created by researchers at the University of Toronto is primarily a vegetarian diet that appears to reduce LDL levels, but without lowering HDL.[48]

Vegetarian Diets

A person who eats a vegetarian diet does not eat meat, poultry, or fish. A vegetarian diet is subclassified as *lacto-ovo-vegetarian*, which includes dairy products and eggs, or *vegan*, which does not contain any animal products. Both types of vegetarian diet can be nutritionally sound throughout the lifespan, including during pregnancy and lactation. Because vegetarian diets are generally lower in saturated fat and higher in fruits, vegetables, and whole grains, this dietary pattern may reduce the risk of some chronic diseases. Population studies of vegetarians have found a lower incidence of obesity, hypertension, type 2 diabetes, and ischemic heart disease and lower rates of low-density lipoprotein cholesterol levels compared to nonvegetarian populations.[49] The incidence of cancer varies widely, however. Although overall the risk of any type of cancer might be lower in persons who have a vegetarian diet, the data on this point are inconclusive.

When consuming a vegetarian diet, attention must be paid to some nutrients that are not found

in large quantities in vegetarian food sources such as vitamin B_{12}, vitamin D, calcium, and n-3 fatty acids. Essential amino acid needs can be met by eating a wide variety of plant foods.

Vitamin B_{12} deficiency is the most common nutrient deficiency in persons who eat a vegetarian diet. Unfortunately, the foods in a typical vegan dietary pattern cannot guarantee uptake of sufficient dietary vitamin B_{12} for normal functioning. Thus, vegans in particular should assiduously supplement their vitamin B_{12} intake with vitamin B_{12}–fortified foods and supplements. Such fortified foods can include vitamin B_{12}–fortified nutritional yeasts, vitamin B_{12}–fortified breakfast cereals, and vitamin B_{12}–fortified meat alternatives.

No food available to a vegan contains adequate vitamin D and calcium. Fatty fish, eggs, and fortified milk are the principal food sources of vitamin D, with sunshine on human skin being the other significant "source" of vitamin D. Therefore, vegans should consider vitamin D supplementation. Vitamin D_3 seems to be the best source of this nutrient.[50] It should be noted that vitamin D_3 may be derived from animals, so a committed vegan might search for a vegan form of vitamin D_3. Vegans appear to have a 30% increased risk of bone fracture risk,[51] so they need to consciously choose fruit and plant sources of calcium. **Table 7-7** lists non-animal sources of calcium. Vegans can also consider a calcium supplement.

It is recommended that to increase n-3 fatty acid intake, vegans and vegetarians should consider supplements containing eicosapentaenoic acid (EPA) and/or docosahexaenoic acid (DHA).[52] Cardiovascular disease appears to be less prevalent among vegetarians, however, even though vegetarians' n-3 fatty acid concentration is often lower than that of omnivores.

Gluten-Free Diet

The number of people choosing a gluten-free diet has increased rapidly in the United States in the last few years, with the latest estimates suggesting that approximately 17% of people living in the United States adhere to a gluten-free diet, including 1.8 million people with celiac disease and 2.7 million people without celiac disease.[53] It is clear that for those persons with celiac disease, adherence to a gluten-free diet decreases inflammation and symptoms of the disease. Although celiac disease and wheat allergy sensitivity are clearly defined disorders related to gluten intake, the existence of non-celiac gluten sensitivity syndrome remains controversial, despite being the subject of several consensus conferences.[54,55] Nevertheless, the midwife should be aware of potential dietary concerns related to a gluten-free diet. Women consuming gluten-free products are at risk for excessive intake of high-glycemic carbohydrates and saturated fat and deficiencies of fiber, vitamin C, vitamin B_{12}, folic acid, and vitamin D as well as calcium, zinc, and magnesium.[55] However, it should be noted that gluten-free pseudo-cereals, such as quinoa and amaranth, have twice the mineral content (including calcium and iron) of traditional cereals. Therefore, the principle of opting for whole-grain forms of food, instead of processed foods, is an important message to communicate.

Women with celiac disease are at increased risk for poor pregnancy outcomes and osteoporosis. The pregnancy-related risks include prematurity, fetal growth restriction, small-for-gestational-age newborns, as well as stillbirth.[56] Women whose disease is well controlled

have a lower risk than those whose disease is not well controlled. Therefore, preconception counseling about a gluten-free diet in these women has the potential to improve their pregnancy outcomes. Additionally, women with celiac disease are at risk for low bone density that may or may not normalize with a gluten-free diet.[56] Emphasizing adequate intake of calcium and vitamin D or supplementation, starting in adolescence, is important for long-term health.

Weight Management Counseling and Dietary Patterns

Numerous morbidities are associated with obesity: metabolic disorders such as diabetes and polycystic ovary syndrome, cardiovascular disease, osteoarthritis, and malignancies. Thus it would seem clear that midwives should assist women with obesity and other weight management concerns. Consistent weight management is a very challenging task for many individuals, however, and the best evidence shows that the kind of low- to moderate-intensity counseling that a busy clinician can provide is not the most effective approach.[57] In addition, community resources such as those that provide a high-intensity comprehensive lifestyle intervention, entailing a minimum of 14 sessions over 6 months, may be unavailable. When a midwife has limited time, direct referral to a dietician or a specific weight management program may be most helpful. The midwife should seek interventions that are short, precisely targeted, easily administered, understandable to women, and validated.

Dietary Assessment

Assessment customarily begins with a calculation of the woman's body mass index (BMI). Web-based BMI calculators can readily be found on the Internet (sources are listed in the Resources section at the end of this chapter), but the calculation involves only simple arithmetic and can be done by hand using the following formula:

$$BMI = [(\text{weight in lbs}) \div (\text{height in in})^2] \times 703 \text{ or}$$
$$BMI = (\text{weight in kg}) \div (\text{height in m})^2$$

For most individuals, including adolescents, a BMI in the "normal" range for their gender is associated with a reduced risk of obesity-related morbidities. However, BMI is not as accurate for postmenopausal women, who have typically lost some muscle mass and, therefore, might have a "normal" BMI but be at higher than normal risk. This assessment technique is also clearly inaccurate for body builders or elite athletes, who have much less body fat than average and, therefore, might have a "high" BMI but actually be at normal or even reduced risk.

Waist circumference in women more than 35 inches (88 cm) has been found to be an additional indicator of increased disease risk. Data reveal that an even better measure to identify persons at risk for cardiovascular disease and diabetes is a waist circumference-to-height ratio of more than 0.5.[58] For example, a waist measure of 37 inches and a height measurement of 65 inches would translate into a ratio of 0.57. The waist-to-height ratio identifies abdominal adiposity in the many different populations in which it has been tested, and the cut-off ratio of 0.5 is applicable in both men and women and in both young and old. The ease, usefulness, and relative accuracy of the waist-to-height ratio argue strongly for making waist circumference measures a regular part of every health assessment examination.

The 2012 weight management and treatment algorithm developed by the National Heart, Lung, and Blood Institute (NHLBI) uses BMI as the decision indicator and is available on the Internet.[57] Within this algorithm, weight management counseling is not advised if a woman is only overweight but lacks any risk factors for diabetes or cardiovascular disease. However, if

she has (1) two risk factors for diabetes and/or cardiovascular disease and (2) a BMI greater than 25 kg/m^2 or waist circumference larger than 35 inches, or a BMI greater than 30 kg/m^2, then she should be asked about her desire to lose weight. If she is ready to make a behavior change, then referral to a comprehensive lifestyle program is recommended, although the counseling may also be undertaken by the provider.

If weight management will be helpful for the woman, the next step should be a brief assessment of her readiness to change. It may be helpful to conceive of the process of weight management as providing *cues* rather than providing *cures*. If and when a woman is receptive, she will receive and welcome a supportive and factual weight management conversation, and be able to consider strategies proposed by the midwife as cues to her own behavior and incorporate them into her life. If a woman is not ready to change, attempts to intervene from a healthcare professional will seem irrelevant, irritating, or even threatening to her as an advertisement for a product or behavior in which she has no interest.

Accordingly, a midwife seeing a woman who meets the NHLBI criteria for weight-loss management might use a few brief questions to obtain a general concept of where the woman is in her journey using the "stages of change" model. A sample question sequence that is supportive, brief, and factual for the stages of change model is found in **Table 7-11**.

Table 7-11 **Sample Question Sequence for the "Stages of Change" Model**

"There's no right or wrong answer to this question, but for me to better understand where you are right now, have you been thinking about losing weight?"
[In response to either yes or no] "That's fine." (That is, briefly give support).
[If yes] "Have you been thinking about a plan?"
[If yes] "Is this something you intend to do soon, like within the month, or is this more of a long-term goal?"
"Would you like me to be involved in this process with you, and be a support for you, no matter what happens?"

Although it would be ideal to have women complete a 24-hour or 3-day food diary prior to their healthcare visit, and then have the time for the woman and the midwife to analyze these data together for macronutrient and micronutrient content, the reality is that busy midwives do not usually have the time to do this kind of counseling. Another option is to ask all women being seen for an initial or annual visit to complete a "Starting the Conversation About Healthy Eating" questionnaire, which incorporates questions to assess readiness to change, along with seven questions to assess dietary patterns (**Figure 7-2**).[7] Three response categories exist for each question; they are scored 0, 1, or 2, starting from left to right, culminating in a range of scores from 0 to 14. Higher scores indicate a poorer dietary pattern. The form includes practical suggestions for each question on how this aspect of eating can be improved. It also includes a section for making goals for changing if a woman is at that stage of change.

ARE YOU READY TO WORK ON **HEALTHY EATING** DURING YOUR PREGNANCY?
___I'm ready to make some changes and I would like help
___I'm not sure if I'm ready to change the way I eat but I would like to start the conversation
___I'm not ready to change the way I eat at this time

HOW WELL DO YOU EAT?	TIPS TO HELP YOU EAT WELL
How many times a week do you eat food that is fried or high in fat? ☐ Less than 1 ☐ 1–3 ☐ 4 or more	**Eat less fast food.** • If you eat fast food, order grilled chicken, a salad, or plain burger.
How many servings of fruit and vegetables do you eat each day? ☐ 5 or more ☐ 3–4 ☐ 2 or less	**Aim for 5 or more servings of fruits and vegetables a day.** • Add a fruit and a vegetable to each meal. • Raw fruits and vegetables are easy snacks.
How many regular sodas, juice, or glasses of sweetened beverages do you drink each day? ☐ Less than 1 ☐ 1–2 ☐ 3 or more	**Beverage calories add up.** • Drink water throughout the day. • If you drink milk, switch from whole or 2% to 1% or skim. • Limit soda and other sweet drinks to one or less per day.
How many times a week do you eat beans (like pinto or black beans), chicken, or fish? ☐ 3 or more ☐ 1–2 ☐ Less than 1	**Eat more beans, chicken, and fish.** • Beans are a great substitute for meat. • Eat up to 12 oz. of low-mercury fish weekly like canned light tuna, salmon, or pollock. • Eat baked, broiled, or grilled chicken and fish. • Avoid high mercury fish like shark, swordfish, king mackerel, and tilefish.
How many times a week do you eat regular (not low-fat) snack chips or crackers? ☐ 1 or less ☐ 2–3 ☐ 4 or more	**Hold the chips.** • Try popcorn, but limit oil, butter, or salt. • Try nuts such as almonds or walnuts, but limit your serving to 2 Tablespoons.
How many times a week do you eat desserts and other sweets? ☐ 1 or less ☐ 2–3 ☐ 4 or more	**Be smart with your sweet tooth.** • Eat smaller amounts of dessert. • Try desserts with less fat and calories like fruit, sherbet, or angel food cake.
How many butter, lard, and animal fat (visible fat in red meat, chicken skin) do you eat? ☐ Very little ☐ Some ☐ A lot	**Cut back on animal fats.** • Use a small amount of plant-based oils and transfat free margarines. • Season foods with spices and fresh herbs.

0 × (____) + 1 × (____) + 2 × (____) = Total Score _____

IF YOU FEEL THIS WAY	TRY THESE THINGS
Healthy food costs too much.	**Eat well can save you money.** • Eat less meat and more beans. • Eat canned or frozen fruits and vegetables. • Eat at home instead of going out.
Healthy food doesn't taste as good as junk food.	**Don't give up your favorite foods—just eat smaller amounts.** • Try new foods and recipes.
I eat when I'm bored, tired, angry, or depressed.	**Find something else to distract you.** • Work on a hobby, call a friend, go for a walk. • Keep only healthy snacks around.
It's hard to be healthy when I eat out.	**Avoid all-you-can-eat places and restaurants that don't offer healthy options.** • Order grilled or low-fat sandwiches and salads instead of fried foods. • Ask for low-fat dressing on the side. • Ask for half portions, share with a friend, or bring leftovers home.

Figure 7-2 Starting the conversation about healthy eating.
Reproduced with permission from Widen E, Siega-Riz AM. Prenatal nutrition: a practical guide for assessment and counseling. *J Midwifery Womens Health.* 2010;55(6):540-549.[7] © 2010, with permission from Wiley.

I eat too much at social events.	**You can still eat healthy at social events.** • Eat a healthy snack before you go. • Choose a few things to eat. • Bring healthy dishes to potlucks.
I eat too much when I'm cooking or cleaning.	**Don't just eat because it is there.** • Chew gum or a toothpick. • Ask someone else to put away leftovers while you wash dishes.
I tend to skip regular meals, but snack in front of the TV and throughout the day.	**Make time for regular meals.** • Sit down at the table and eat healthy meals with friends, family, and/or co-workers. • Pack lunch and snacks to take to work or for travel.

Making a plan
What goal(s) can you set for yourself now? **Before my next visit, I am going to:** ___ Eat fried foods less often ___ Aim to eat 5 or more fruits and vegetables per day ___ Eat smaller portions ___ Instead of regular sodas, juice, and sugar sweetened beverages, drink water or skim milk ___ Keep healthy snacks around ___ Other _____

A more comprehensive and validated instrument is the easy-to-use "Rapid Eating and Activity Assessment for Patients" (REAP), which contains 31 questions. The accompanying "REAP Physician Key for Diet Assessment and Counseling" provides clear directions for further assessment, treatment, and counseling based on responses to each of the questions.[59] All behavioral changes must be made by the woman herself, in a manner that she can freely accept and commit to. Weight is a delicate subject for many women, and repeatedly offering warm support rather than remedies will build trust. When specific plans and strategies seem relevant to discuss, offering a woman cues to become more active in her weight management rather than imposing cures should be the goal. Cures are imposed; cues are freely accepted or freely put on hold. Finally, if the woman will be seeing the same healthcare provider again, this provider can offer continuing support. It is important for the midwife to take into account and be supportive of weight management failures as well as successes, as both may occur. Repeated, honest, and realistic offers of support "no matter what happens" can help build the needed trust.

While a weight-loss intervention can be part of the nutritional choices made by a woman for herself (in consultation with her healthcare provider), the more fundamental issue remains adopting one of the healthier dietary patterns discussed previously in this chapter. The healthiest and safest weight-loss "diets" usually involve following the same healthier dietary patterns that would be recommended for anyone, with the modification of eating smaller portions, so as to create a daily calorie deficit in the range of 500–750 kcal/day. A minimum

weight-loss goal to improve an individual's health has been shown to be 5%. A woman attempting a weight loss should be offered a follow-up assessment with the midwife or another clinician after 6 months. At the 6-month visit, the clinician can evaluate weight loss, review behaviors the woman has attempted to change, and reinforce these efforts. It is important to initiate plans with the woman to maintain her weight loss, since weight loss usually plateaus at this time. To reiterate, a midwife can remind a woman that learning and adopting a healthier dietary pattern will be valuable to her throughout her life, whatever her weight, and whatever her health and life goals.

Women who are unable to meet a healthy weight goal with diet and exercise, especially after attempting intensive comprehensive lifestyle programs, may be candidates for pharmacologic therapy or referral for possible bariatric surgery. Weight-loss drugs work by suppressing appetite, limiting fat, or altering neurotransmitters such as serotonin and catecholamines that regulate appetite and food intake in the central nervous system. Currently there are five FDA-approved drugs for long-term weight loss, listed here in order of their relative weight loss results from smallest to largest mean amount of weight lost:

1. Orlistat (Xenical or Alli, over the counter at a lower dose) is a lipase inhibitor and the oldest drug on the market.
2. Lorcaserin (Belviq) is a Schedule IV drug due to its potential hallucinogenic properties.
3. Phentermine and topiramate combination therapy (Qsymia) is contraindicated for use during pregnancy and is also a Schedule IV drug.
4. Liraglutide (Saxenda), a drug also used for type 2 diabetes, is available only as an injectable.
5. Naltrexone/bupropion (Contrave) is the newest option on the market. Expected weight loss over 12 months ranges from 6 to 9 kg (13–20 pounds).[60]

Women with BMIs greater than 40 kg/m^2, and women with BMIs between 35 and 40 kg/m^2 who have a comorbidity such as hypertension, hyperlipidemia, diabetes, or obstructive sleep apnea, should be offered a referral to a bariatric surgeon in addition to a comprehensive lifestyle program.[56] Bariatric surgery has been shown to be the most successful strategy for weight loss for this population of women.[61] Additionally, recent evidence demonstrates that women who are obese and experiencing infertility (undergoing assisted reproductive technologies) increase their ability to conceive and have a live birth by one-third following bariatric surgery compared to attempts prior to surgery.[62]

Nutrition Across the Lifespan

Nutritional needs change significantly over the course of a woman's lifetime. A review of nutrition and recommended nutrition and counseling for women during pregnancy and nutrition specific to lactating women are addressed in the *Prenatal Care* and *Breastfeeding and the Mother–Newborn Dyad* chapters. This chapter focuses on nutrition during non-reproductive phases in a woman's life.

Nutrition During Adolescence

Adolescence is a period of rapid physical growth and, therefore, high nutritional need. During adolescence, females gain 40% of their skeletal mass and 50% of their body weight. Inadequate nutrition, especially calcium intake, can compromise their peak bone mass. Unfortunately, the diet pattern of adolescents tends to be poor due to the consumption of calorie-dense, nutrient-poor foods; it is also a time when teenage girls typically stop drinking milk. Of perhaps greatest concern is the increased rate of obesity among U.S. children and adolescents. Today, on average, 20% of girl teens are obese, and such an increase in body fat has both health and social implications.[63]

In recent decades, the age of onset of puberty has decreased. The reasons for this trend may include increased exposure to environmental pollutants and chemicals, stress, and increased body fat in childhood. For every one-point increase in BMI, menstruation occurs 1 month earlier.[64] Stage 2 or greater breast development is now not uncommon at ages 7 and 8 years, with its rate ranging from 18% to 43%; black girls have a higher rate of this condition than white girls.

Beyond body fat, type of food consumed plays a role in the development of puberty. Data from national surveys show that the onset of puberty is delayed approximately 7 months in children consuming large amounts of plant protein, whereas those with a high intake of animal protein enter puberty approximately 7 months earlier.[64] Also, greater isoflavone intake—which is found in soy products, chickpeas, and lentils—delays breast development by 7 months. Earlier onset of puberty can pose significant self-image and social problems for young children, who may be seen as more socially and emotionally mature than they actually are.

By developing a young girl's trust and conducting the same kind of sensitive assessment as previously outlined to determine whether she is ready to make at least small alterations in her diet or exercise patterns, a midwife can play a role in helping her establish healthier diet patterns for life. Problem-solving barriers to change for an adolescent must include consideration of where and when food is consumed, especially if in the presence of peers, and the adolescent's ability to control the kinds of food purchased and prepared at home. The two nutrients essential at this phase of development are calcium and iron, as the intake of both of these nutrients tend to be low in adolescents.

Nutrition, the Menstrual Cycle, and Fertility

Nutrition also affects, and is affected by, the menstrual cycle. Studies suggest that caloric

intake varies during the menstrual cycle, peaking once in the luteal phase and once in the follicular phase, and reaching a nadir during menses.[65] These changes are theorized to coincide with cyclical fluxes in a woman's basal metabolic rate that are affected by hormones. Women also appear to increase their intake of carbohydrates and fat during the luteal phase, and their intake of protein and fat in the follicular phase, as compared to the menstrual phase. Women with premenstrual syndrome have similar intakes as women without this condition, but increase their intakes of non-milk sugars and alcohol in the luteal phase.[53] Women with very low body fat become anovulatory.

According to the Centers for Disease Control and Prevention, 1 million married women in the United States are infertile, with six times that number having a reduced fecundity.[66] Women at the extremes in body weight are more likely to have reduced fertility. Therefore, aiming for a healthy body weight is important for improving fertility. Data from the Nurses' Health Study indicate that for women with high BMIs, losing 5% to 10% of body weight may improve ovulation, especially if regular exercise is incorporated into the regimen.[67] Lean women who exercise strenuously should reduce this activity to a moderate level to improve their fertility. Other specific dietary patterns associated with improved ovulatory fertility from the Nurses' Health Study—beyond those emphasized in this chapter, such as eliminating trans fats and eating low-glycemic carbohydrates—include choosing more plant-based proteins, and temporarily trading nonfat or low-fat dairy products for the full-fat versions.

Nutrition and the Mature Woman

As women age, they may find that their abdominal fat and weight increase. Although this change in perimenopausal women is due to a combination of genetics, age, and physical activity, some evidence indicates that loss of estrogen contributes to the redistribution of fat to the abdominal area in middle age and later. Increased abdominal fat increases women's risk for cardiovascular disease and type 2 diabetes. Mature women also become increasingly at risk for osteoporosis, which makes adequacy of vitamin D and calcium levels important. Therefore, a healthy eating pattern is important to this population of women to maintain their quality of life.

Many studies have focused on the use of individual nutrients, particularly isoflavones, to help manage hot flashes. Unfortunately, most systematic reviews have not found these therapies to be effective when tested against placebo, although many studies may be of too short duration to adequately test the comparisons.[68]

Nutrition and Selected Conditions

Eating Disorders

An estimated 5% of all women in the United States may have, or have had, some form of eating disorder, although fewer than half seek treatment for this condition.[69] Primary care providers may not automatically recognize eating disorders. Due to the difficulties of detection and the complex etiology of eating disorders, successful detection, diagnosis, and treatment require a multidisciplinary effort by a team of health professionals, preferably with special education in the field. Although midwives in busy practices may lack education for in-depth counseling and treatment of women with eating disorders, they should be able to rule out some instances of eating disorders through use of a brief screening and provide follow-up referrals when necessary.

The SCOFF is a brief five-question instrument with a high negative predictive value in the general population. That is, when used among a normal clinical population, the SCOFF questionnaire is not reliable in detecting eating disorder, but it is reliable in ruling it out.[70] "SCOFF" is a mnemonic for the five questions found in the questionnaire. The questions assess whether individuals are making themselves vomit to relieve a feeling of fullness (S); whether they are concerned that they have lost control over what or how much they eat (C); whether they have recently lost a significant amount of weight (15 pounds or more) (O); whether they feel that they are "fat" even when others comment that they are thin (F); and whether they feel that thoughts and feelings about food are dominating their life (F). An answer of "yes" to two or more questions is indicative of an eating disorder. The SCOFF has been validated as an effective screening tool to screen for eating disorders.[70] Two questions from the SCOFF that may be particularly associated with pica (another eating order) are the two "F" questions related to feeling fat and thinking a lot about food.[71] Individuals with some symptoms of disordered eating should be assessed in more detail by professionals in the area.

Cancer

Numerous studies of every type have been undertaken to identify the role of diet in the development of cancer. Most of the intervention trials that tested supplements with selected vitamins or minerals have yielded disappointing results in terms of these nutrients' ability to prevent cancer. This fact underlies the USPSTF finding that there is no evidence to support routine vitamin/mineral supplementation to prevent cancer. One reason for these disappointing results has already been discussed in this chapter—namely, that the totality of what we eat, including both macronutrients and micronutrients, exerts a powerful physiologic effect, probably more powerful than just providing a single supplement without changing the overall dietary pattern.

That said, strong evidence from World Cancer Fund International links overweight/obesity or excess abdominal fat to 11 different cancers, including breast, endometrial, and ovarian cancers.[72] This organization notes especially strong evidence that the consumption of nonstarchy vegetables and fruits is protective against mouth, esophageal, stomach, and lung cancers. Colorectal cancer is the cancer for which the strongest evidence shows that what we

eat or do not eat matters. Along with exercise, dietary fiber, garlic, milk, and calcium consumption have preventive effects related to colorectal cancer, whereas consumption of red meat, processed meat, and alcohol, along with greater body and abdominal fat, increase the risk of this cancer. Unfortunately, for breast and reproductive cancers, there is not strong evidence that diet plays a role in their development, beyond the indication that greater body or abdominal fat increases the risk of postmenopausal breast cancer and endometrial cancer. For premenopausal breast cancer, breastfeeding is protective and alcohol use increases risk.

Age-Related Eye Disease

Macular degeneration and cataracts are two eye-related conditions that women may develop as they age. Strong evidence shows that consumption of vegetables and fruits rich in lutein and zeaxanthines, which accumulate in the eye, may protect against free-radical damage to the eye caused by smoking, pollution, sunlight, and metabolism from an unhealthy diet pattern such as consumption of a high-glycemic diet.[73] Spinach, kale, and brightly colored fruits and vegetables are rich in these nutrients. Additionally, higher B vitamin intake is associated with decreased cataracts.[74]

Conclusion

Research increasingly confirms that good nutrition is essential during all phases of life, and the basic principles of good nutrition remain remarkably consistent throughout the life course. Albeit with some caveats, good nutrition is good nutrition—for women who are pregnant, or who want to lose weight, gain weight, or maintain their weight. The midwife should understand the basics of nutrition and how dietary patterns affect normal physiology. Nutrition counseling should be gently incorporated into a midwife's regular practice so that each woman can understand some basic principles of nutrition, the physiologic response of the body to ingested food, and current evidence-based dietary guidelines. Although understanding individual components of the diet is important for health professionals, counseling a woman about diet should remain positively focused on the types of preferable foods to eat and the need to eat a variety of foods, rather than emphasizing individual macronutrients and micronutrients. Of course, a midwife should also be prepared with nutrition information specific to pregnancy, be alert to the possibility of eating disorders and refer women appropriately in such cases, and be ready with encouragement, factual information, and possible referral if a woman indicates a desire to achieve a healthier weight.

CHAPTER

8

Mental Health Conditions

BARBARA W. GRAVES

Mental health disorders affect millions of individuals and families in the United States. Primary care providers, including midwives, care for women who are affected by mental health disorders, either as a sole disorder or comorbid with other illnesses. This chapter presents an overview of mental health conditions that commonly affect women; a framework for identification of common disorders; and screening strategies for determining the need for urgent referral to a mental health expert. An introduction to treatment modalities for many of the most common conditions is included.

Controversy exists regarding use of the terms “mental health” and “behavioral health.” Since no clear consensus is available, this chapter uses the term “mental health.” Substance use, which may be included under the umbrella of behavioral health, is reviewed in the *Common Conditions in Primary Care* chapter.

Mental health disorders are the most common and costly cause of disability in the United States.[1,2] Almost one third of persons who reside in the United States will suffer from an anxiety disorder in their lifetime, and between 15% and 20% will experience a major depressive episode.[3] Unfortunately, many individuals with mental health disorders do not seek treatment, and of those who do, many are not able to access the mental health system due to widespread shortages of mental health providers or lack of financial resources. Members of uninsured, underinsured, low income and minority populations are the least likely group to receive treatment.[3]

Mental health disorders affect more than the individual; they also affect entire families. This phenomenon is especially true when women have such disorders, as they are most often the primary care providers for children. In addition, women are at risk for mental health disorders that are hormonally associated such as premenstrual mood disorder, perinatal and postpartum mood disorders. **Figure 8-1** presents the lifetime prevalence of selected mental health

disorders in men and women.[3] A cross-national survey of 72,933 individuals in Africa, Asia, Europe, the Middle East, and the Americas found that among all cohorts in all countries, women had an odds ratio (OR) of 1.9 (95% confidence interval [CI], 1.8–2.0) for experiencing depression and an OR of 1.7 (95% CI, 1.6–1.8) for experiencing an anxiety disorder when compared to men. No significant gender difference was found among those with a bipolar disorder, and the difference for social phobia (OR, 1.3; 95% CI, 1.2–1.4) was less than other anxiety disorders.[4]

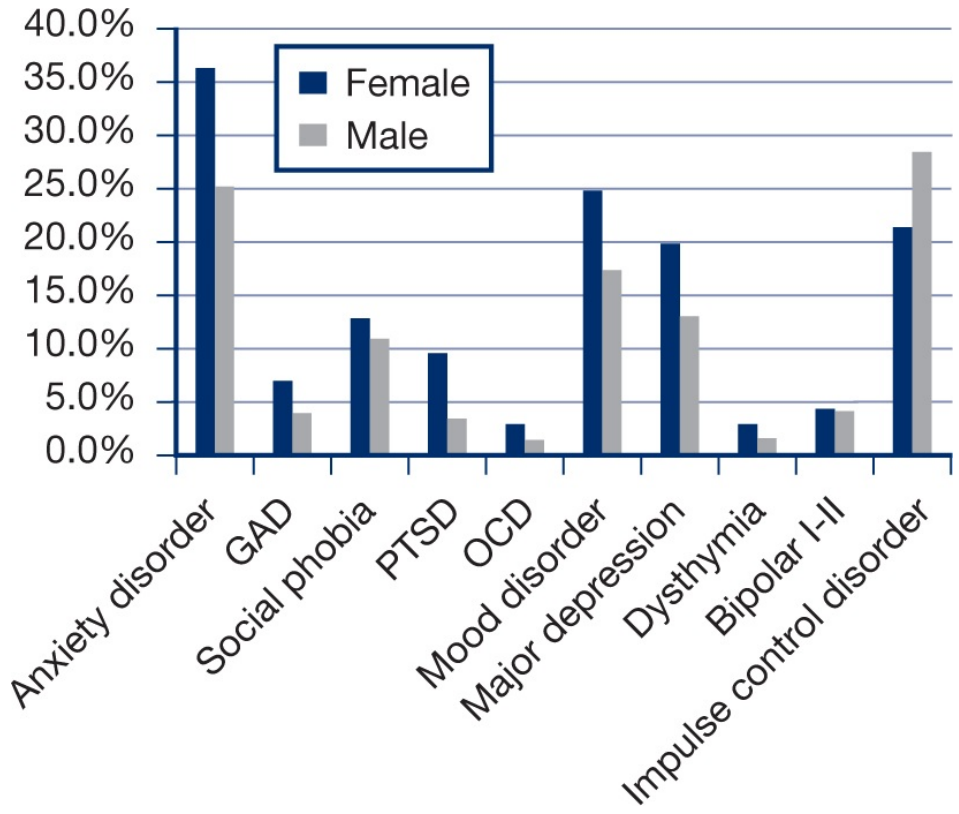

Figure 8-1 Lifetime prevalence of selected disorders identified in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (*DSM-IV*) from the World Mental Health Survey version of the Composite International Diagnostic Interview.

Abbreviations: GAD, generalized anxiety disorder; OCD, obsessive–compulsive disorder; PTSD, post-traumatic stress disorder.

Data from Kessler RC, Berglund P, Demler O, Jin R, Merikangas KR, Walters EE. Lifetime prevalence and age-of-onset distributions of *DSM-IV* disorders in the National Comorbidity Survey Replication. *Arch Gen Psychiatry.* 2005;62(6):593-602.[3]

The etiology of mental disorders is complex, with genetic,[5] epigenetic, and environmental factors all intertwined.[6] The two most frequently encountered mental health disorders in primary care are depression and anxiety, both of which are multifactorial in origin. Twin studies have found that genetic factors are a significant contributor to the development of both major depression and anxiety disorders, although perhaps more for depression than for anxiety.[7]

Attenuation appears to diminish the influence of genetics as individuals move from childhood to adulthood.[8-10] Genetics appears to have a greater influence in women than in men,

owing to hormonal shifts related to puberty, menstruation, and childbearing that influence both the neurologic and immune systems. Women are also more likely than men to exhibit somatic symptoms associated with mood disorders.[2] Environment and experiences are equally important in determining whether an individual will develop depression or anxiety. Culture plays a significant role in the meaning an individual assigns to mental illness and the ways in which symptoms present. Environmental risk factors include childhood adversity such as poor parental attachment, witnessing or experiencing trauma, and subsequent stressors such as relationship problems and poor social support. Brain imaging studies have demonstrated altered connectivity between the limbic system, including the amygdala, and the frontal cortex among individuals with mood disorders.[7,11,12]

The diagnostic standard for psychiatric disorders is the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*). This manual has evolved as knowledge about mental health has increased, with the most recent revision as of this writing, the fifth edition *DSM-5*, being published in 2013.[13] *DSM-5* delineates specific diagnostic criteria for each distinct psychiatric diagnosis, and is the reference for the tables throughout this chapter.

The management of women with major mental health disorders, such as schizophrenia, bipolar disorder (BPD), obsessive–compulsive disorder (OCD), and eating disorders, is beyond the scope of care for most primary care practitioners. The role of the midwife in caring for women with one of these disorders is usually to perform screening and referral. In contrast, midwives working as primary care providers may diagnose, initiate, and perhaps, continue treatment for women with depression, including perinatal and postpartum depression, and some women with anxiety disorders. Although most primary care providers do not have the training for counseling or therapy, they often can prescribe or renew psychopharmacologic medications and recommend lifestyle changes, as well as work in concert with psychiatric professionals. Proper education is necessary to prescribe psychotropic medications appropriately and safely.

Screening for Mental Conditions

The U.S. Preventive Services Task Force recommends that all adults, pregnant women, and women who recently gave birth be screened for depression.[14] Several screening tools are available for use in clinical practice and those commonly used are presented in this chapter. Some depression screening instruments may miss detection of individuals with other psychiatric disorders, so it is important to choose the tool that is best for the population being screened.

A recently developed questionnaire, the M-3 Checklist, is a 23-item checklist that screens an individual for depression, anxiety disorders, and bipolar disorder, and includes questions specific to functional impairment secondary to their symptoms. The validity and feasibility of this tool were examined using a study population that included 723 English-speaking individuals attending a family medicine clinic, 647 of whom completed all aspects of the study. Participants completed the M-3 Checklist while waiting to be seen by their clinician; they also answered a brief exit questionnaire about the checklist. The checklist was completed in less than 5 minutes. A master's-prepared diagnostic interviewer contacted each participant by phone within 30 days of the visit to administer the Mini Neuropsychiatric Interview (MINI); the mean time from the clinic visit to the follow-up phone call was 8.8 days. The checklist was scored in a two-step method, beginning with functional impairment, which eliminated 53.9% of the population who would be eliminated from further scoring. This first step would have eliminated approximately 11% who met the MINI criteria for a psychiatric diagnosis. Of the participants who passed this "gateway," 62.4% of the remaining group were diagnosed with a psychiatric disorder. In total, 36.4% of the participants were diagnosed with one or more psychiatric disorders. Among the participants, 4.2% were diagnosed with depression without anxiety, 12.1% with depression and anxiety, 9.1% with anxiety without depression, and 9.3% with bipolar disorder. The sensitivity, specificity, positive likelihood ratio, and negative likelihood ratios for depression, bipolar disorder, anxiety, and post-traumatic stress disorder (PTSD) were comparable to the corresponding statistics for single-disorder screening instruments.[15]

Overview: Psychotherapy and Pharmacotherapy

The two primary therapeutic modalities for mental health disorders are psychotherapy and pharmacotherapy. Several different forms of psychotherapy exist, and several different classes of drugs have effects on the neurotransmitters relevant to mental health disorders. For some conditions, such as depression, a combination of pharmacotherapy and psychotherapy is most effective as treatment; for others, such as anxiety disorders, psychotherapy is more effective than pharmacotherapy.

Psychotherapy

In brief, psychotherapy helps individuals understand emotions, behaviors, and ideas that contribute to their mental disorder, and identifies ways to help modify emotions, behaviors, and/or ideas. Therapy can be conducted individually, in groups, or for families. **Table 8-1** presents an introduction to the primary forms of psychotherapy used to treat the most common mental health conditions that a midwife may identify in clinical practice.

Table 8-1 Common Types of Psychotherapy

Therapy	Description	Conditions for Which Effectiveness Is Established
CBT	Well-established, effective short-term therapy. Focus is on identifying and changing thinking and behavior patterns. Benefits are usually seen in 12–16 weeks. Therapy may involve reading and keeping records between therapy sessions.	Depression[a] Anxiety disorders Eating disorders Phobias
Exposure therapy	A form of CBT. Exposure therapy is used to reduce anxiety and fear responses via gradual or simulated exposure to the anxiety-provoking stimulus.	Phobias Obsessive–compulsive disorder
Dialectical behavioral therapy	A blend of CBT and Eastern meditation that focuses on combining acceptance and change. May include individual and group therapy. Originally developed for persons with suicidal thoughts. Useful for anyone with high emotional reactivity.	Depression[a] Panic disorder Post-traumatic stress disorder Eating disorders Obsessive–compulsive disorder
Interpersonal therapy	Limited structured therapy usually delivered over a 16-week period. Focuses on how interpersonal difficulties affect mental health and, in particular, depression.	Depression[a]
EMDR	Eye movements can reduce the intensity of disturbing thoughts. EMDR may be similar to what happens during REM sleep.	Post-traumatic stress disorder Panic attacks Phobias

Abbreviations: CBT, cognitive-behavioral therapy; EMDR, eye-movement desensitization and reprocessing; REM, rapid eye movement.

[a] Includes perinatal depression.

Cognitive-behavioral therapy (CBT)—a time-limited therapy that aims to change maladaptive patterns of thinking and behaviors—has been the subject of the most research and is effective for treating individuals with major depressive disorders and anxiety disorders. Topics, or "lessons," for sessions often include psychoeducation, behavioral activation, cognitive restructuring, problem solving, graded exposure, relapse prevention, and assertiveness skills. While CBT has traditionally been delivered by mental health specialists, the scarcity of such providers has limited its impact. More recently, CBT has also been delivered or supported by primary care providers, specially trained nurses, and social workers. In this approach, CBT may be delivered on a face-to-face basis, via the Internet, or as a computer-based therapy.

Pharmacotherapy

Psychotropic medications used to treat mood disorders and anxiety disorders include antidepressants, tricyclic antidepressants, and anxiolytics. These medications primarily affect the neurotransmitters serotonin, norepinephrine, and dopamine, either singly or in combination. Although neurotransmitters have many complex functions, they exert those functions only when released into the synaptic space between neurons. Thus, antidepressants such as selective serotonin reuptake inhibitors (SSRIs), which block reuptake of the neurotransmitter into the presynaptic neuron, will augment the effects of that neurotransmitter. Drugs that decrease anxiety are called *anxiolytics*. Benzodiazepines such as alprazolam (Xanax) are very effective for reducing anxiety but have a risk of dependence and tolerance so must be used with caution. This chapter presents a broad overview of these therapies for midwives who may collaborate with a mental healthcare professional in the care of women with mental disorders.

Mood Disorders

Mood disorders include forms of depression known as dysthymia (a mild, chronic depression) and major depressive disorder (MDD); bipolar disorder; and premenstrual dysphoric disorder. MDD is the most common mood disorder among adults in the United States, and is four times more prevalent than either dysthymia or bipolar I/II. While dysthymia and bipolar disorders are less prevalent, each of these disorders is associated with significant suffering and financial costs for individuals, families, and society.[16]

Figure 8-2 presents a simplified algorithm that can aid the differential diagnosis of mood disorders. This algorithm is based on a thorough process that is outlined in the *DSM-5*.[13,17] Note that, in some situations when mood disorders and anxiety disorders are discussed together, there is a tendency to use abbreviations when documenting health care visits. Perinatal mood and anxiety disorders should not be referred to using the acronym PMAD due to the negative connotations associated with this term.

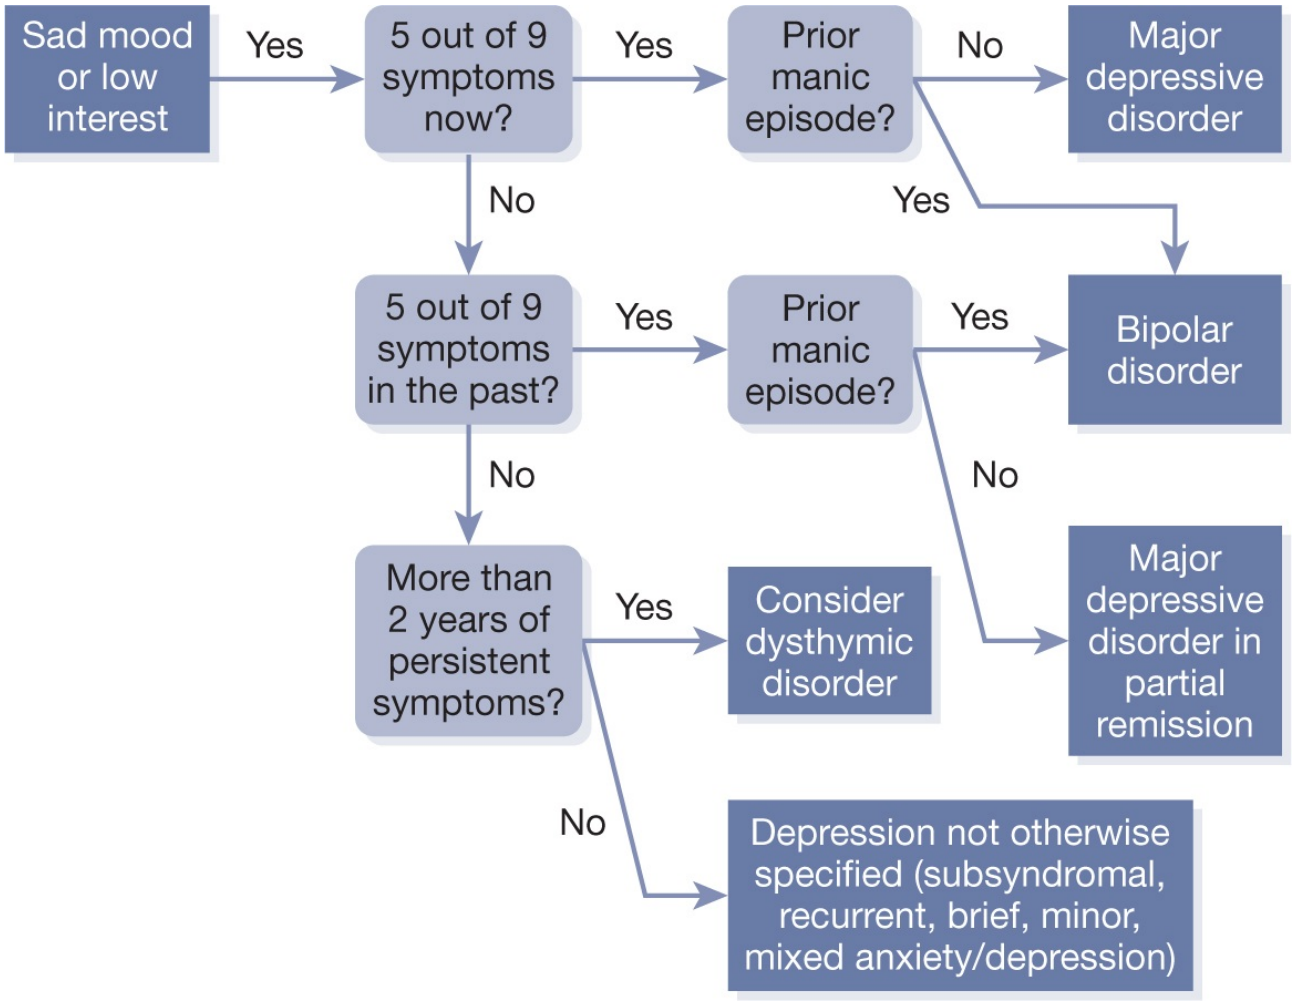

Figure 8-2 Differential diagnosis of mood disorders.

Reproduced with permission from U.S. Department of Health and Human Services. *Depression in Primary Care: Volume 1. Detection and Diagnosis.* AHCPR Publication No. 93-0550. Rockville, MD: Agency for Health Care Policy and Research; 1993:20.[17]

Depression

Depression affects millions of persons in the United States. Approximately 16.6% of the U.S. population have a major depressive disorder during their lifetime.[3] When Wittayanukorn et al. analyzed a sample of adults who completed the National Health and Nutrition Examination Survey (NHANES) between 2007 and 2010, they found that 9.8% met the criteria for moderate to severe depression.[18] An additional 15.8% of respondents reported symptoms of mild depression.[18] Women are at an increased risk compared to men, as are individuals who are ethnic minorities, living in poverty, or lacking adequate health insurance. Additional risk factors are listed in **Table 8-2**.

Table 8-2	Risk Factors for Major Depression
Stressful life events such as divorce, job change, or financial problems	
Recent death of a loved one or friend	
Family members with depression	
History of abuse or trauma	
Exposure to traumatic event (e.g., car accident, hurricane)	
Intimate-partner violence	
A serious or chronic medical condition	
Alcohol or drug abuse	
Prior episodes of depression	
Many medications may contribute to depression or cause symptoms of depression	

Depression has a major impact on quality of life and the ability to work and is second only to back and neck pain as the cause of disability days.[19] Depressive disorders are often associated with other comorbid conditions such as chronic disease, and may lead to decreased quality of life for those whose health conditions are aggravated by depression.[20] Depressed individuals may also have other psychiatric disorders, including personality disorders, anxiety disorders such as obsessive–compulsive disorder, eating disorders, and substance abuse disorders.

Women with combined diagnoses, including those exhibiting any psychotic features such as delusions or hallucinations, require specialist mental health services. They should be referred appropriately by the midwife.

Depression is the mental health disorder most frequently diagnosed by primary care providers. Even so, it is common for depression to be undiagnosed or treated suboptimally depending on the demands of the practice and attitudes of the provider. A 2012 systematic review of studies that invesigated the diagnosis of depression made by nonpsychiatric physicians found that the diagnosis of depression was missed more than half the time. Only 24% of those individuals with major depression are estimated to receive treatment, with only 9% receiving adequate therapy.[21]

The diagnostic criteria for major depression and dysthymia are described in **Table 8-3**.

Individuals with mild major depression will present with the minimum of symptoms that meet the diagnostic criteria; those with moderate depression exhibit more symptoms, but typically are able to carry out their usual activities; and those with major depression often exhibit difficulty even when performing normal activities.[22,23]

Table 8-3 **Common Depressive Disorders**

Major Depression

Symptoms (SIGECAPS)

Symptoms must include either depressed mood or anhedonia (lack of interest) PLUS any of the following symptoms (to total five symptoms), which occur nearly every day for at least 2 weeks, and are severe enough to impede function:

1. **S**leep disorder (insomnia or hypersomnia)
2. **I**nterest deficit or a lack of feeling pleasure
3. **G**uilt (worthlessness, hopelessness, regret)
4. **E**nergy deficit (fatigue or loss of energy nearly every day)
5. **C**oncentration deficit
6. **A**ppetite disorder (increased or decreased), unplanned weight loss or gain
7. **P**sychomotor retardation or agitation
8. **S**uicidality (recurrent thoughts of death)

There has never been a manic or hypomanic episode.

Symptoms are not attributable to a medical condition or substance use.

Must be qualified as a single episode or recurrent.

Dysthymia

Symptoms

Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years.

Presence of two or more of the symptoms listed under major depression.

There has never been a manic or hypomanic episode.

Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders.* 5th ed. Arlington, VA: American Psychiatric Association; 2013*13*; Hackley B, Sharma C, Kedzior A, Sreenivasan S. Managing mental health conditions in primary care settings. *J Midwifery Womens Health.* 2010;55(1):9-19.*22*

Women with bipolar disorders (defined in **Table 8-4**) may also present with depression. However, depression associated with bipolar disorder is distinct from unipolar depression. It is extremely important to also screen for mania or hypomania when screening for depression, because treating women who have bipolar disorder with antidepressants can aggravate the manic condition. While management of women with depression may fall within the scope of primary care, individuals with symptoms of mania or hypomania should be referred to a mental health specialist.

Table 8-4 **Bipolar Disorder**

Diagnosis includes major depression AND history of mania (bipolar I) or hypomania (bipolar II), leading to a marked impairment in occupational function, social activities, or relationships; may lead to hospitalization or psychotic features. The manic phase must last a minimum of 7 days.
Symptoms of Mania
Inflated self-esteem or grandiosity
Decreased need for sleep
More talkative than usual or pressure to continue talking
Flight of ideas or feels thoughts are racing, agitation
High energy, irritability, or pleasure-seeking
Must have three symptoms (or four, if the only symptom is irritability) during the time of mood disturbance.
Symptoms of Hypomania
Lasts a minimum of 4 days
Briefer duration and less severe symptoms
Associated with unequivocal change in functioning that differs from normal function for that individual
Not severe enough to cause marked impairment in social or occupational functioning
Not associated with psychosis

Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013[13]; Hackley B, Sharma C, Kedzior A, Sreenivasan S. Managing mental health conditions in primary care settings. *J Midwifery Womens Health.* 2010;55(1):9-19.[22]

Screening for Depression

The U.S. Preventive Services Task Force and other professional organizations recommend regularly screening women for depression and establishing a system for referring individuals to mental health services.[15] Several screening instruments can be used to assess for depression, ranging from a questionnaire with two questions to a questionnaire that has 21 items.

The Patient Health Questionnaire-2 (PHQ-2), the two-question instrument (**Table 8-5**), was developed and validated in New Zealand, and has a sensitivity of 97% (95% CI, 83–99%) and a specificity of 67% (62–72%).[24] The likelihood ratio for a positive test with the PHQ-2 was found to be 2.9 (95% CI, 2.5–3.4), and the likelihood ratio for a negative test was 0.05 (95% CI, 0.01–0.35).[25] Adding a third question about whether the individual desires help for the depression improved the specificity of the original two questions[26] but may decrease the sensitivity, with the ultimate result that some individuals who are depressed may not be identified.[27]

Table 8-5 **PHQ-2: Two-Question Screen for Depression[a]**

Over the 2 weeks how often have you been bothered by any of the following problems?	Not at All	Several Days	More Than Half the Days	Nearly Every Day
Little interest or pleasure in doing things	0	1	2	3
Feeling down, depressed, or hopeless	0	1	2	3

Abbreviation: PHQ-2, Patient Health Questionnaire-2.

[a] The PHQ-2 score ranges from 0 to 6. A cut off score of 3 is optimal for screening purposes.

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt Kroenke and colleagues, with an educational grant from Pfizer Inc. Available at: http://www.phqscreeners.com.

Management for individuals who respond positively to either question on the PHQ-2 depends on the expertise of the clinician and the resources of the setting for management of mental health disorders. If either of these is lacking, the clinician should screen for immediate risk of harm to the individual or others; if no risk for harm is present, the clinician should refer the woman to an appropriate mental health provider.

The PHQ-9 (**Table 8-6**) is available in the public domain, has nine items, and is commonly used for monitoring response to treatment as well as screening for depression.[28] Depression screening can be conducted quickly, using a two-step screening process. A woman is asked the two questions of the PHQ-2, which is then followed up with the PHQ-9 as needed. This two-step screen provides a balance of sensitivity and specificity.[29] The midwife can then provide primary care or refer the woman to a mental health specialist depending on available resources. Additional screening for depression should include an evaluation for conditions or diseases that may be causing the depression. Thyroid function tests are indicated, and possibly a complete blood count to evaluate for anemia. Drug screening may be indicated as well.

Table 8-6 **PHQ-9: Nine-Question Screen for Depression**

Over the last 2 weeks, how often have you been bothered by any of the following problems? (use "x" to indicate your answer)	Not at All	Several Days	More Than Half the Days	Nearly Every Day
1. Little interest or pleasure in doing things	0	1	2	3
2. Feeling down, depressed, or hopeless	0	1	2	3
3. Trouble falling or staying asleep, or sleeping too much	0	1	2	3
4. Feeling tired or having little energy	0	1	2	3
5. Poor appetite or overeating	0	1	2	3
6. Feeling bad about yourself or that you are a failure or have let yourself or your family down	0	1	2	3
7. Trouble concentrating on things, such as reading the newspaper or watching television	0	1	2	3
8. Moving or speaking so slowly that other people could have noticed; or the opposite—being so fidgety or restless that you have been moving around a lot more than usual	0	1	2	3
9. Thoughts that you would be better off dead, or of hurting yourself in some way	0	1	2	3
	Column Totals	____	____	____
	TOTAL SCORE	____		

10. If you checked off any problems, how difficult have those problems made it for you to do your work, take care of things at home, or get along with other people?

☐ Not difficult at all ☐ Somewhat difficult ☐ Very difficult ☐ Extremely difficult

Total Score	*Depression Severity*
1–4	Minimal depression
5–9	Mild depression
10–14	Moderate depression
15–19	Moderately severe depression
20–27	Severe depression

- Consider a depressive disorder if there are at least four "x" marks in the shaded section (including Questions 1 and 2). Add up the score to determine severity.
- Consider a major depressive disorder if there are at least five "x" marks in the shaded section (one of which corresponds to Question 1 or 2).
- Consider another depressive disorder if there are two to four "x" marks in the shaded section (one of which corresponds to Question 1 or 2).

Abbreviation: PHQ-9, Patient Health Questionnaire-9.

Question 10 Note: All responses should be verified by the clinician. Diagnoses of major depressive disorder or other depressive disorder also require impairment of social, occupational, or other important areas of functioning (Question 10) and ruling out normal bereavement, a history of a manic episode (bipolar disorder), and a physical disorder, medication, or other drug as the biological cause of the depressive symptoms.

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt Kroenke and colleagues, with an educational grant from Pfizer Inc. Available at: http://www.phqscreeners.com.

The Center for Epidemiologic Studies-Depression Scale (CES-D), Patient Health Questionnaire-2 (PHQ-2), Patient Health Questionnaire-9 (PHQ-9), Beck Depression Inventory (BDI), and Edinburgh Postnatal Depression Screen (EPDS) have all been validated, and have sensitivities ranging from 0.8 to 0.9, and specificities from 0.7 to 0.85. All of these instruments are written at the sixth-grade level and are easy to complete, and several can be completed and scored online. The accuracy of the questionnaires appears comparable for identifying individuals with depression.[29] While all of these instruments have been widely

employed for depression screening, each has some benefits and some detractors. In particular, although the EPDS has been extensively validated for use during pregnancy and the postnatal time period,[30] it has not been validated for use outside the perinatal period. The BDI is copyrighted, and requires a fee for each use. The CES-D is the longest of the commonly used screening instruments for depression.

Suicidal Ideation and Intent

The midwife should always assess for suicidal ideation in women who have screened positive for depression and in anyone who expresses a sense of hopelessness. Common statements that are red flags for suicidal ideation include "Life is not worth living;" "My family would be better off without me;" "I won't be around to deal with that;" "I would be better off dead;" and "There is nothing I can do to make this better." Women at highest risk for suicide include those who have a specific plan or have access to the means to commit suicide, such as guns, cutting, or prescription or street drugs. Other risk factors include previous hospitalization or suicide attempt; family history of suicide; sense of hopelessness; experiencing family, romantic, or legal conflicts; social isolation; and insomnia.[31]

Screening instruments used to identify individuals at risk for suicide are listed in the Resources section at the end of this chapter. Although no single instrument is considered the best, or even the most frequently used, they all address the questions listed in **Table 8-7**. The midwife has a responsibility to refer any woman deemed at risk for suicide to emergency mental health services.[32]

Table 8-7 Questions to Assess for Suicidal Ideation and Intent

Question	Clinical Notes
1. Are you currently thinking about or have you recently thought about death or harming yourself?	If answer is yes, consider additional questions that assess frequency, intensity, and duration of suicidal ideation
2. Have you thought about how you would harm yourself?	If answer is yes, consider additional questions that assess frequency of suicidal thoughts about a possible method of suicide
3. Do you have access to a method such as gun and bullets or pills?	If answer is yes, consider additional questions that assess location of methods
4. Do you have any intention of following through with thoughts of self-harm?	If answer is yes, consider additional questions that assess: • Preparatory acts (e.g., collected pills, wrote a suicide note, obtained a gun) • Rehearsals for suicide (e.g., loading gun) versus nonsuicidal self-injurious acts

Additional Questions
What has kept you from acting on these thoughts?
What are your plans for the future?
Have you or a family member ever attempted suicide in the past?
Are you currently using drugs or alcohol (illicit or prescription)?
Have there been any changes in your employment, social life, or family?
Do you have friends or family with whom you are close? Have you told anyone that you have these thoughts?
Do you tend to be impulsive with your decisions or behavior?

Dysthymia Versus Major Depression

The term *dysthymia* comes from a Greek word meaning "bad state of mind" or "bad humor."

Dysthymia is a chronic form of depression in which the symptoms are neither as severe nor as numerous as they are in major depression. This disorder has been identified in cultures worldwide, although the prevalence appears to be higher in high-income countries when compared to low- to middle-income countries.[33] Dysthymia can be just as disabling as major depression due to its chronic nature even though its symptoms are less severe.

Similar to major depression, dysthymia occurs more commonly in women, and is often underdiagnosed except when complicated by comorbid major depressive episodes.[34] The lifetime community prevalence is between 3% and 6%, although a higher prevalence between 5% to 15% has been noted in primary care settings.[35] While the specific depressive symptoms may be less severe, dysthymia may be associated with slower and less complete recovery than major depression.[35] It is not uncommon for an individual with dysthymia to experience a major depressive disorder, a phenomenon known as "double depression."[36]

Treatment of Depression: General Principles

Many treament modalities exist for women with depression, including cognitive-behavioral therapy, counseling, faith-based therapy, group work, and psychotropic medications. Regardless of treatment modality selected, the goal is remission of symptoms. Education and recommendations for sleep hygiene, participation in pleasurable activities, and exercise are beneficial adjuncts.[32]

Evidence-based guidelines for the management of depression on the Internet are available for primary care providers and are listed in the Resources section at the end of this chapter. Complementary treatments that have been found to be efficacious as adjuncts to psychotherapy or medication include omega-3 fatty acid supplementation, *S*-Adenosyl methionine (SAMe), bright light therapy, massage, yoga, and acupuncture.[37] While some evidence suggests that St. John's wort (*Hypericum perforatum*), an herbal/botanical product, may benefit individuals with mild or moderate depression, products containing it are not regulated for purity or consistent dosing. In addition, St. John's wort is known to interact with many medications, including other antidepressants, protease inhibitors used for treatment of human immunodeficiency virus (HIV) infection, and combined oral contraceptives.

Medication and nonpharmacologic therapy are associated with similar rates of initial improvement, but individuals treated with medication alone are more likely to experience relapse compared to those treated with therapy.[38] Treatment with both nonpharmacologic therapy and psychotropic medication appears to result in the best remission rates. Current guidelines published in the United States recommend psychotherapy and pharmacotherapy together for treatment of MDD when possible.[32] The combination of both pharmacotherapy and psychotherapy improves the likelihood of remission and decreases the risk of relapse.[32,38–40] If combined therapy is not available, psychotherapy is recommended for persons with mild to moderate MDD, with pharmacotherapy being added if there is no response to the nonpharmacologic therapy.[32] Pharmacotherapy should be the initial therapy for anyone with severe major depression.[32] Gender does not appear to influence the response to cognitive-behavioral therapy as compared to the response to drug therapy.[39] The decision to initiate treatment with psychotherapy or medication is based on many factors, such as preferences of the individual, severity of depression, access to and acceptability of counseling, insurance coverage, and the individual's ability to commit to the time involved in therapy.[41]

Several studies have suggested that antidepressant therapy is more effective for treatment of dysthymia than for MDD. In 2011, Levkovitz et al. published the results of a meta-analysis of trials comparing antidepressants to placebo in persons with a diagnosis of MDD or dysthymia. Antidepressant therapy was more effective than placebo for persons with dysthymia (relative risk [RR], 1.75; 95% CI, 1.42–2.04; $p < 0.0001$).[41] In addition, the response to placebo in persons with dysthymia was lower than the response to placebo in persons with depression, further validating the effect of antidepressants for this population.[42] While interpersonal psychotherapy may be useful for persons with dysthymia,[43] it is not believed to be as effective as pharmacotherapy.[44]

The University of Washington's Advancing Integrated Mental Health Solutions (AIMS) Center has developed the IMPACT model, which recommends a team approach to following individuals who are diagnosed with depression.[45] Implementation of collaborative care using this model, which involves a case manager (either a specially trained nurse or social worker) and a psychiatrist, has been found to improve outcomes when compared to usual care.[46] The case manager educates the woman about depression, monitors depression symptoms, coaches her in behavioral activation and pleasant-event scheduling, encourages physical activity, and supports the mutually agreed-upon plan of care with close follow-up; in addition, the case manager may provide initial adjustments to medication dosages. The case manager also helps in coordinating referrals and reinforcing follow-through. The psychiatric consultant regularly reviews all cases in which improvement does not occur as expected and is available for consultation for any specific concerns.

Psychotherapy

Several types of psychotherapy are available for treating persons with MDD. To date, cognitive-behavioral therapy has the most evidence for effectiveness.[42] Most midwifery practices are not structured to provide ongoing psychotherapy. Nevertheless, the midwife's

responsibility for follow-up continues even after referral to a mental health specialist to ensure that the woman who has depression has not stopped therapy prior to achieving remission. The midwife may be in a unique position to provide targeted time-limited counseling from having developed an ongoing therapeutic relationship with the woman. This relationship provides an opportunity to discuss behaviors that may improve depression symptoms, such as an exercise program[32,47] and engaging in pleasurable activities. Bright light therapy has been shown to be effective in treating depression that has a seasonal component, and has benefits as an adjunct therapy for individuals with nonseasonal depression as well.[37]

When discussing psychotherapy, the woman can be reassured that therapy is short-term in nature for most persons with depression. Although the strongest evidence supports CBT, behavioral activation and interpersonal therapy have also been found to be effective, and both are recommended by the Canadian Network for Mood and Anxiety Treatments (CANMAT) as first-line psychological acute treatments for depression.[48] Early studies of Internet-delivered psychotherapy with guidance from a therapist have been promising. A recent meta-analysis concluded that Internet-based CBT intervention has superior short-term effectiveness compared to controls, although there is inadequate research to evaluate its long-term effectiveness.[49]

Pharmacologic Therapies

Due to the challenges of entering into psychotherapy, many individuals with depression will opt to initiate pharmacotherapy rather than counseling. Prior to beginning pharmacotherapy for depression, it is critical that the clinician has ruled out bipolar disorder, as treatment with an antidepressant may trigger mania,[50] suicidal ideation, or psychosis in persons with this condition.[51] During screening to rule out bipolar disorders, important signs include a family history of bipolar disorder, risky behaviors, legal issues, history of taking multiple antidepressants without improvement, history of suicide attempts, and a history of agitation or irritability while taking antidepressants in the past.[52]

Psychotropic medications affect the three neurotransmitters that modulate mood—dopamine, serotonin, and norepinephrine. **Figure 8-3** depicts the effects and interactions of these neurotransmitters.[51] Second-generation antidepressants, which include SSRIs, norepinephrine–dopamine reuptake inhibitors (NDRIs), and serotonin–norepinephrine reuptake inhibitors (SNRIs), are the first-line medications for treating depression.[52] The overall effects of SSRIs are considered modest.[52] In addition, most psychotropic medications have some adverse effects that can lead to discontinuation of the medication. Thus the cost–benefit ratio for an individual woman can be difficult to determine.

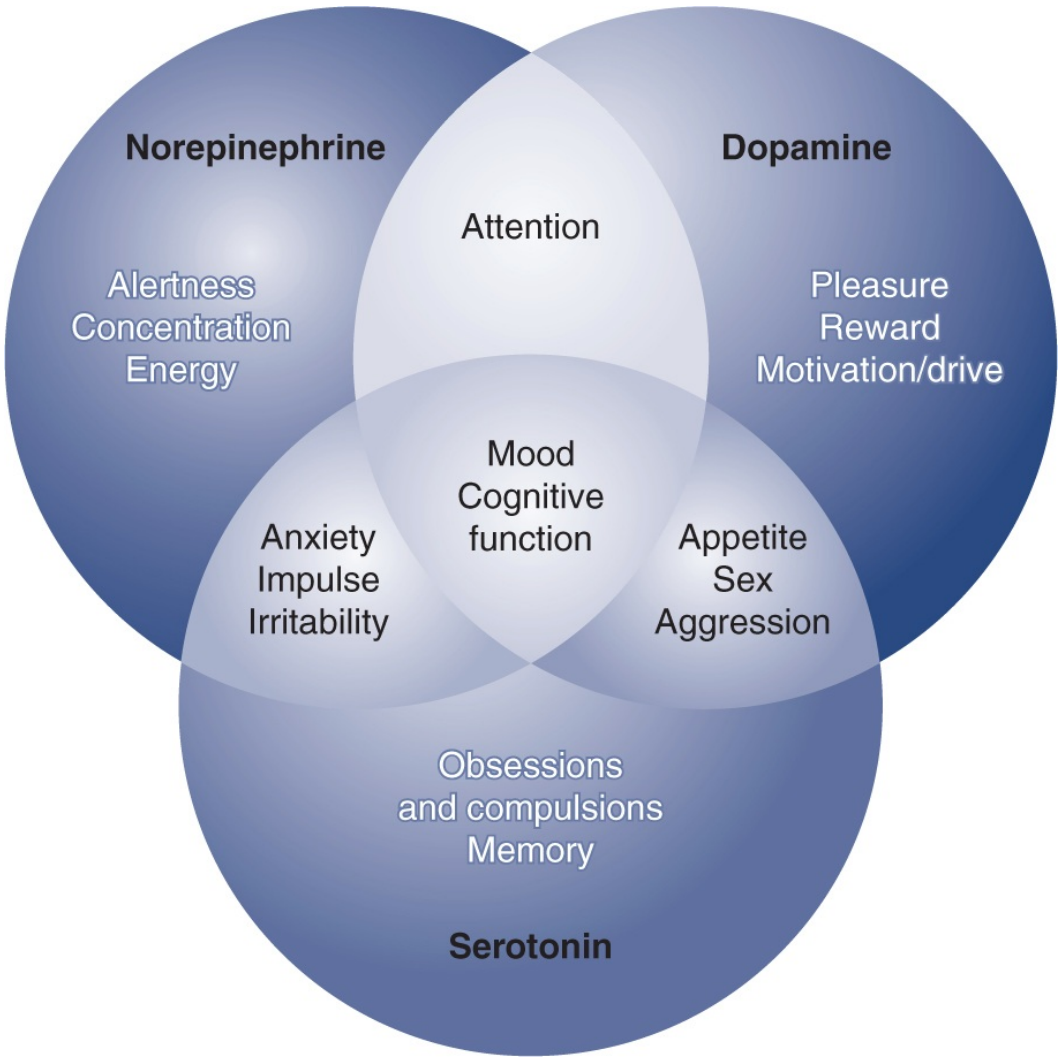

Figure 8-3 Role of dopamine, norepinephrine, and serotonin.

Reproduced with permission from Early NK. Mental health. In: Brucker MC, King TL, eds. *Pharmacology for Women's Health*. 2nd ed. Burlington, MA: Jones & Bartlett Learning; 2017:727-764.[51]

Some providers may opt to prescribe bupropion (Wellbutrin, Zyban), an NDRI that has less effect on sexual function compared to SSRIs. Bupropion, however, lowers the threshold for seizures, so it should not be used with other medications that also lower the seizure threshold or for individuals with risk factors for seizures. Bupropion has no effect on anxiety, and may even aggravate anxiety.[53]

Classes of drugs that have been used in the past for depression, and may be prescribed by psychiatric clinicians in specific situations, include monoamine oxidase inhibitors and tricyclic antidepressants. These older medications have a narrow therapeutic range, potential for high toxicity, and serious interactions with many foods and other medications; thus, they are rarely prescribed by primary care providers.

The SSRIs are metabolized through the CPY450 enzyme system. As such, they interact with a wide variety of other medications that are metabolized by the same system. Some of the specific medications that are known to interact with these second-generation antidepressants include older antidepressants such as tricyclic antidepressants, digoxin (Lanoxin), warfarin

(Coumadin), anticonvulsants, beta blockers, cisapride (Propulside), and theophylline (Theo-Dur).[51] Prior to prescribing any psychotropic medication, the clinician is responsible for reviewing all the medications the woman is taking so as to avoid potentially serious interactions.

Research has failed to demonstrate significant differences in effectiveness among the various SSRIs, SNRIs, or NDRIs.[54] Nevertheless, individual medications in these classes do have different side-effect profiles, as summarized in **Table 8-8**.[55,56] The choice of which medication should be used to initiate therapy is based on the individual's preference, past successful treatment with a specific medication, and the predominate symptoms that accompany the depression. For example, all the SSRIs may be associated with weight gain, but fluoxetine (Prozac) is more activating, while sertraline (Zoloft) is less so.[55–58] Thus, fluoxetine would be a better choice to treat a woman with hypersomnia and low energy. As a group, the SNRIs are less frequently associated with weight gain than SSRIs.[22] The woman's ability and motivation to follow therapeutic recommendations is another consideration in selecting which SSRI or SNRI to use when initiating treatment. Abrupt discontinuation of SSRIs or SNRIs usually leads to serotonin withdrawal (or discontinuation) syndrome, whose symptoms include dizziness, ataxia, agitation, headache, tremor, and confusion.[22] Fluoxetine has the longest half-life of the second-generation antidepressants, and it may be the most appropriate medication for those who may have difficulty taking their pills consistently.

Table 8-8 **Antidepressant Medications Prescribed by Primary Care Providers**

Generic Agent (Brand Name)	Starting Dose	Dosage Range and Maximum Dose	Side-Effect Profile	Pharmacokinetic Half-life
Selective Serotonin Reuptake Inhibitors				
Citalopram (Celexa)	20 mg/day for 7 days, then may increase to 40 mg/day. Maintain initial dose for 4 weeks before increasing it.	20–40 mg/day	Minimal drug interactions. Weight gain is common, and more likely after 6 months of use. Good choice for women with anxiety and women who are pregnant. May cause QT prolongation. Lowest risk for liver toxicity; higher risk for sexual dysfunction.	Half-life of 35 hours; few metabolites
Escitalopram (Lexapro)	10 mg to start Increase to 20 mg if partial response after 4 weeks.	10–20 mg/day	Minimal drug interactions. Weight is gain common, and more likely after 6 months of use. Good choice for women with anxiety and women who are pregnant. May cause QT prolongation.	Half-life of 27–32 hours
Fluoxetine (Prozac)	10–20 mg/day May increase to 20 mg/day after 7 days Maintain at 20 mg/day for 4–6 weeks; then 30 mg for 2–4 weeks before additional increases.	20–80 mg/day	May worsen anxiety. Higher risk for switching to the mania phase if the woman has bipolar disorder. Lowest risk for sexual dysfunction. Weight gain is common, and more likely after 6 months of use. More activating than other SSRIs.	Longer half-life of 3–4 days; long elimination of active metabolites. Withdrawal symptoms are less likely than with all other SSRIs.
Paroxetine (Paxil)	10–20 mg/day for 7 days May increase dose by 10 mg/week	Maximum dose: 50 mg/day	Not recommended during pregnancy. Weight gain is more likely than with other SSRIs; may be sedating. Higher risk for sexual dysfunction. Anticholinergic. Recommended for women who breastfeed.	Short half-life; no active metabolites. Users are more likely to experience serotonin withdrawal symptoms.
Sertraline (Zoloft)	25–50 mg for 7 days, then may increase in 25-mg increments	Maximum dose: 200 mg/day	Weight gain is common, and more likely after 6 months of use. Limited CPY450 interactions. Mildly stimulating. Recommended for women who breastfeed.	Half-life of 2–4 days; some minimally active metabolites. Withdrawal symptoms are less likely.
Selective Norepinephrine Reuptake Inhibitors				
Duloxetine (Cymbalta)	20–60 mg as one or two doses/day 30 mg/day for 7 days, then may increase to 60 mg/day	Maximum dose: 60 mg/day	Weight-neutral in the short term; uncertain if weight gain occurs in the long term. Fewer sexual side effects than some SSRIs in the short term; no long-term difference. No impact on blood pressure.	Half-life of 12 hours. Withdrawal symptoms have been reported, but their frequency is unknown.

Venlafaxine (Effexor)	37.5 mg	75–300 mg/day in 2–3 divided doses	Weight-neutral. Fewer sexual side effects than SSRIs. Increases blood pressure in a dose-dependent fashion. More agitation and gastrointestinal side effects than SSRIs.	Withdrawal symptoms have been reported. Frequency of withdrawal symptoms is unknown.
Venlafaxine IR	37.5 mg	37.5–300 mg/day		
Norepinephrine–Dopamine Reuptake Inhibitors				
Bupropion (Wellbutrin, Zyban)	200 mg in divided doses, twice daily	450 mg in 4 divided doses. Single dose should not exceed 150 mg.	May be stimulating. No sexual side effects. Weight-neutral or minor weight loss. Lowers seizure threshold	Half-life is 29 hours for sustained release. Withdrawal symptoms have not been reported.
Bupropion SR (Wellbutrin SR)	300 mg in divided doses, twice daily	Maximum dose: 400 mg given in divided doses, twice daily. Single dose should not exceed 200 mg.		

Abbreviations: IR, immediate release; NDRI, norepinephrine–dopamine reuptake inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitor; SR, sustained release; SSRI, selective serotonin reuptake inhibitor.

Available at: https://www.healthquality.va.gov/guidelines/MH/mdd/. Accessed July 22, 2017.[56]

Side Effects of Psychotropic Medications

Once the clinician has made the diagnosis of major depression and ruled out bipolar disorder, the decision to begin psychotropic medication is made jointly with the woman. All of the SSRIs and SNRIs may cause gastrointestinal upset, jitteriness, and headache after initiation, as the body adapts to the higher levels of neurotransmittors. Within approximately 2 weeks, the receptors are desensitized and downregulated, leading to the disappearance or significant decrease in these side effects.[51] Unfortunately, these adverse side effects often occur prior to a therapeutic effect becoming evident, and may lead the woman to discontinue the medication. Psychotropic drugs should be initiated at a low dose for the first 1 to 2 weeks to minimize these symptoms. The lower dose, when accompanied by anticipatory guidance, will improve the likelihood of the woman continuing the medication.

Adverse Effects of Psychotropic Medications

Serotonin syndrome is a potentially life-threatening reaction that results from excess serotonergic activity. Although it remains rare, its incidence is suspected to be rising due to the more frequent prescribing of serotonergic medications, the potential for overdose, and a possible toxic reaction when therapeutic doses of an SSRI or SNRI are potentiated by an

interaction with other agents. In 2005, 8585 cases of serotonin syndrome were reported in the United States with moderate to major, but not life-threatening, effects; in addition, 118 deaths were attributed to serotonin syndrome.[59] As many as 16% of individuals who overdose on SSRIs develop serotonin syndrome.[60] Combining treatment with more than one SSRI or SNRI, monoamine oxidase (MAO) inhibitors, lithium, or concurrent use of St. John's wort may precipitate serotonin syndrome and should be avoided. Some other classes of drugs—such as triptans, anticonvulsants, and some opioids—also have serotonergic activity. Many recreational drugs, including amphetamines, cocaine, and ecstasy, can trigger serotonin syndrome as well.

Signs and symptoms of serotonin synrome include autonomic instabilty such as hypertension or hypotension, hyperthermia, tachycardia and tachypnea, and diaphoresis; changes in mental status, including agitation, confusion, or hypomania; and neuromuscular changes such as myoclonus, hyperreflexia, tremor, ataxia, and rigidity.[61,62] The clinical manifestations can be highly variable, however, and referral of women who are suspected of experiencing serotonin syndrome to the emergency department is appropriate.[61,62]

The risk of suicide and suicide attempts has been found to increase during the first 1 to 2 months after beginning treatment with SSRIs, especially among adolescents and young adults.[63] In 2004, the U.S. Food and Drug Administration (FDA) placed a black box warning on these agents' labels for providers who prescribe SSRIs for children, adolescents, and young adults, younger than 25 years.[63] Depression is also associated with suicide attempts and because these medications can take several weeks to become effective, close monitoring is indicated for the first few months after therapy is initiated for all persons.

Follow-up and Monitoring

Ongoing monitoring of psychotropic medications is recommended at least monthly until full remission is achieved, and then every 2 to 3 months. Response to and side effects from the many SSRIs, SNRIs, and NDRIs vary greatly, and most women will require adjustments to the initial dose. Monitoring should begin within 1 to 2 weeks after initiating therapy, which can be accomplished either by phone or in a face-to-face visit. This encounter is an important time to discuss whether the individual has filled the prescription, begun taking it, and is continuing the medication, and if not, to identify the barriers or reasons. This first follow-up visit allows for assessment of side effects and possible increases in suicidal thoughts or behaviors.

Some women may experience an improvement in their depression by their 1- to 2-week visit, although many will not appreciate a response until as late as 6 weeks after beginning medication. It is recommended that a reassessment of depressive symptoms be repeated 4 to 8 weeks after initiating therapy. Repeat use of the screening instrument employed during the initial diagnosis allows the provider and the woman to determine whether the woman has achieved an objective, quantifiable response to the therapy.

Follow-up enables several assessments to be made, including how the woman is taking the drug, barriers to appropriately taking the medication, and side/adverse effects. The undertreatment of women with depression may be evidence of failure to provide the necessary follow-up. A partial response to treatment may be an indication that an increase in the dose of

the antidepressant is needed. If the woman has less than a 25% decrease in symptoms, either an increase in the dose or a switch to a different antidepressant is appropriate. Referral for concurrent psychotherapy may be useful as well. Further treatment of women who fail to respond is best managed with either referral to or in consultation with a psychiatric provider.

The initial goal is for the woman to experience a 50% reduction in symptoms within 10 to 12 weeks. Complete remission from depression would mean a score of less than 5 on the PHQ-9. **Table 8-9** provides guidance for alterations in management based on the woman's response to the PHQ-9.[20]

Table 8-9 **Using the PHQ-9 to Assess Clinical Response to Treatment of Depression**

PHQ-9 Score	Treatment Response After 4 Weeks	Treatment Plan
Drop of 5 points from baseline	Adequate	No treatment change needed. Follow up in 4 weeks.
Drop of 2–4 points from baseline	Possibly inadequate	May warrant an increase in antidepressant dose.
Drop of 1 point or no change or increase	Inadequate	Increase dose of medication; augmentation; switch; informal or formal psychiatric consultation; add psychological counseling.

Abbreviation: PHQ-9, Patient Health Questionnaire-9.

Based on Unützer J, Park M. Strategies to improve the management of depression in primary care. *Prim Care*. 2012;39(2):415-431.[20]

All clinicians who care for women with depression have the responsibility to follow the response to complete remission, as adequate treatment decreases the risk of relapse.[64] Inadequate treatment is a continuing concern. Stepped care—similar to the stepped care used for asthma management—is a strategy to assess ongoing improvement, and adjust the treatment regimen if the woman is not moving toward full remission.[20]

Relapse

Relapse is common in persons who suffer from depression, with 20% to 85% of depressed individuals experiencing a second episode of depression within 2 years of the initial episode.[45] The risk of relapse is lower when antidepressant therapy is continued for 4 to 9 months after remission has been achieved, for a total duration of 6 to 12 months.[14,20,21,57] Individuals who have had or are at high risk for relapses will benefit from more long-term maintenance therapy. Characteristics of women for whom maintenance therapy should be considered are listed in **Table 8-10**. These women should be encouraged to continue therapy for at least 2 years, during which time provider–woman interactions may take place every 3 to 12 months as long as the woman's mental health status remains stable.[14,20,45,53] Due to the chronic nature of dysthymia and risk of episodes of double depression, many women with this disorder will benefit from ongoing, or even lifelong, treatment.[65]

Table 8-10	Indications for Possible Maintenance Antidepressant Therapy
Residual symptoms after adequate treatment	
Persistent sleep disturbance	
Family history of mood disorders	
Ongoing psychosocial stressors	
Three or more previous episodes of major depression	
Two or more closely spaced episodes	
Dysthymia	
Dysthymia with an episode of major depression (double depression)	

Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013[13]; MacArthur Initiative on Depression and Primary Care. Depression management tool kit. 2009. Available at: http://www.integration.samhsa.gov/clinical-practice/macarthur_depression_toolkit.pdf. Accessed July 22, 2017.[55]

Discontinuing Psychotropic Medications

When a decision is made to discontinue psychotropic medications, the dose should be tapered over several weeks to months to avoid serotonin withdrawal syndrome.[32] It is beneficial to provide women with information regarding discontinuation when initiating therapy, as otherwise they may consider stopping the medication without consulting their provider. This caution should be reinforced at each follow-up encounter.

Anxiety and Stress Disorders

Anxiety disorders, a group of disorders characterized by anxiety and/or fear, include generalized anxiety disorder (GAD), panic disorder, and phobias (e.g., social anxiety disorder, specific phobias, and agoraphobia). Phobias are the most prevalent subcategory of anxiety disorders. Stress disorders and obsessive–compulsive disorders were previously categorized as anxiety disorders, but have been recategorized in *DSM-5* as separate categories —"Obsessive–Compulsive and Related Disorders" and "Trauma and Stressor-Related Disorders," respectively, with the latter category including PTSD.[13] As a group, anxiety disorders are more prevalent than mood disorders in the United States, yet they are less often screened for or detected in primary care practices.[66] Women are almost twice as likely as men to experience both anxiety and mood disorders.[4,66] Anxiety disorders cause significant stress; lead to impairment of social, family, or occupational functioning; and are out of proportion to any actual threat.

There are significant racial and ethnic disparities in the prevelence of anxiety disorders in the United States.[67] Most of the research on anxiety has been conducted with European-white participants, yet persons from underrepresented groups are less likely to have access to mental health services, are more likely to have comorbid conditions, and are differentially exposed to many of the risks for anxiety.[67] These factors need to be taken into consideration by clinicians, as they have significant effects on affected individuals.

All anxiety disorders, including OCD and PTSD, are frequently compounded by other anxiety or mood disorders—more so than other psychiatric disorders.[68] It is also common to have a three-way interaction that involves anxiety disorders, depression, and somatic symptoms, including respiratory disease, irritable bowel syndrome, chronic pain or malaise, fatigue, atopic disorders, and even cardiac disease. Anxiety disorders are highly internalizing conditions, which contributes to the associated somatic complaints.[68] Individuals with anxiety disorders may experience such somatic symptoms as palpitations, chest pain, shortness of breath, and dizziness that mimic symptoms of other diseases or conditions and lead to increased healthcare utilization and reduced quality of life.[68]

The reported lifetime prevalence of anxiety and its related disorders varies considerably from 14% to 33% perhaps secondary to different survey techniques and populations used as samples in the various studies.[69,70] The prevalence of other anxiety disorders also varies. Based on surveys administered in 2001 to 2003, lifetime prevalence rates in the United States are 13% for social anxiety disorder, 10.3% for PTSD, 4.1% for GAD, 2.7% for OCD, and 6.8% for panic disorder.[69,70]

Phobias and obsessive–compulsive disorder typically develop during childhood, adolescence, or early adulthood. Panic disorders and generalized anxiety disorder have significant variations in age of onset, as does post-traumatic stress disorder, due to the fact that trauma may occur at any age. Neuroimaging data suggest a significant neurobiological contribution to the development of anxiety disorders.[71]

While much public effort has been made to identify individuals with major depression, less attention has been directed at screening for individuals with anxiety disorders. An approach

for evaluation of a suspected anxiety disorder that is recommended by the British Association for Psychopharmacology is presented in **Figure 8-4**.[68] The *DSM-5* includes a more complex algorithm that captures all the possible differential diagnoses,[13] but this version can be helpful for initial screening performed by a midwife.

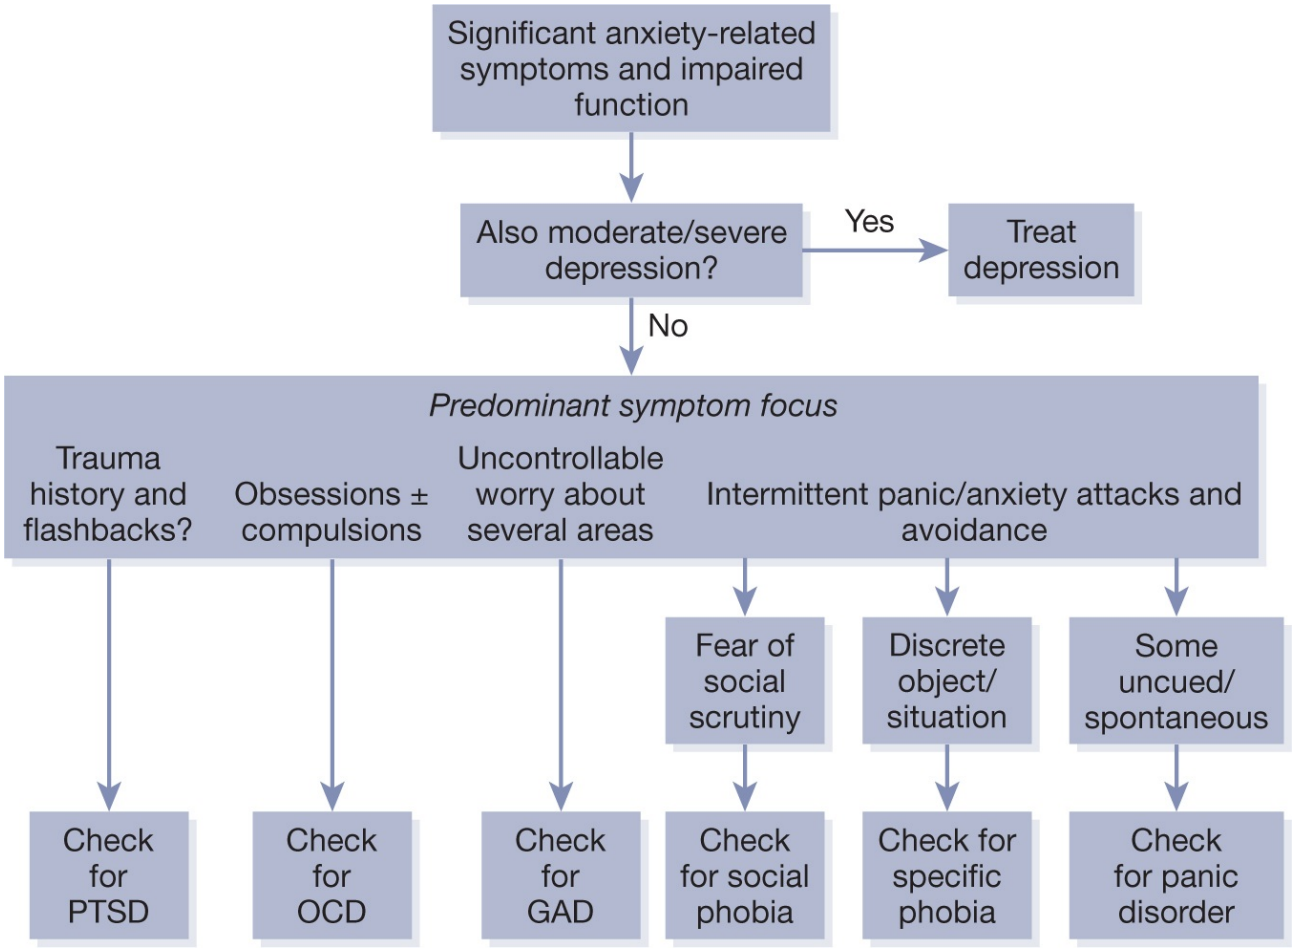

Figure 8-4 One scheme for exploration of a suspected anxiety disorder.

Evidence-based pharmacological treatment of anxiety disorders, post-traumatic stress disorder and obsessive-compulsive disorder: a revision of the 2005 guidelines from the British Association for Psychopharmacology. *J Psychopharmacol.* 2014;28(5):403-439.[68] Reprinted by permission of SAGE.

Screening for Anxiety Disorders

Anxiety disorders are underdetected and, therefore, undertreated. Similar to the PHQ-2 and PHQ-9 screening instruments, the GAD-2 and GAD-7 questionnaires **(Table 8-11)** have been developed and validated as means to screen for anxiety disorders. While the GAD-7 was initially developed specifically to screen for GAD, it has since been validated as a screen panic, social anxiety, and post-traumatic stress disorder, too.[72] This instrument was also found to be equally effective at screening among four racial/ethinc groups of undergraduate students:

African American, Caucasian, Hispanic/Latino, and Asian.[73] The GAD-2 questionnaire consists of the first two questions of the GAD-7, with a score 3 or higher suggesting the presence of an anxiety disorder.

Table 8-11 GAD-7: Generalized Anxiety Disorder Screening Tool

Over the last 2 weeks, how often have you been bothered by the following problems?	Not at All	Several Days	More Than Half the Days	Nearly Every Day
1. Feeling nervous, anxious, or on edge	0	1	2	3
2. Not being able to stop or control worrying	0	1	2	3
3. Worrying too much about different things	0	1	2	3
4. Trouble relaxing	0	1	2	3
5. Being so restless that it is hard to sit still	0	1	2	3
6. Becoming easily annoyed or irritable	0	1	2	3
7. Feeling afraid as if something awful might happen	0	1	2	3
Column Scores	_____	_____	_____	_____

Total Score (add column scores) _____

Scores of 5, 10, and 15 are cut-off points for mild, moderate, and severe anxiety, respectively.
Further evaluation is recommended for a score ≥ 10.

Developed by Drs. Robert L. Spitzer, Janet B.W. Williams, Kurt Kroenke, and colleagues, with an educational grant from Pfizer Inc. Available at: http://www.phqscreeners.com.

Phobias

A phobia is described as extreme or irrational fear or anxiety about a specific object or situation. This fear or anxiety is persistent, lasting more than 6 months.[13] Social anxiety disorder, also referred to as social phobia, is a specific phobia related to social situations in which the individual is exposed to potential scrutiny by others.[13] Studies suggest that phobias can be caused by a traumatic experience or may be learned behavior within a family environment. Maternal stress, overprotection, hypercriticism, abuse, and neglect may all contribute to the development of social phobia.

Generalized Anxiety Disorder

Generalized anxiety disorder is characterized by excessive worry or anxiety concerning family, health, finances, and work or school. A majority of women with GAD also experience other mental health disorders—most commonly depression or dysthymia, but also panic disorder and agoraphobia. As with all anxiety disorders, women are at greater risk for GAD compared to men.[74] Generalized anxiety disorder is associated with numerous somatic symptoms, leading to frequent primary care, specialist, and emergency department visits, and

absences from work.[74]

Generalized anxiety is characterized by the following signs:

- Excessive anxiety and worry (apprehensive expectation) about two (or more) domains of activities or events (e.g., family, health, finances, and school/work difficulties) occurs on more days than not, for 3 months or more.
- Anxiety and worry are difficult to control.
- Anxiety and worry are associated with restlessness and/or muscle tension.
- Anxiety and worry are associated with marked avoidance of activities or events with possible negative outcomes, excessive time and effort preparing for activities or events with possible negative outcomes, marked procrastination in behavior or decision making due to worries, and repeatedly seeking reassurance due to worries.[13]

Panic Attacks

Panic attacks are periods of intense anxiety or fear that have a sudden onset. Although these attacks can be expected to occur in the presence of a particular trigger, they can also be unexpected. The symptoms of a panic attack are dramatic and usually frightening to the person who is experiencing the event. The attack usually peaks at approximately 10 minutes, but full recovery can take days. Symptoms can include sweating, trembling or shaking, sensation of shortness of breath or smothering, nausea, chest pain or discomfort, dizziness, lightheadedness, unsteadiness or fainting, fear of losing control or going crazy, fear of dying, paresthesia, and chills or hot flashes. Individual attacks may occur in conjunction with any of the anxiety disorders, although the presence of recurrent attacks is characterized as panic disorder.[13]

Panic Disorder

The primary symptom of panic disorder is recurrent unexpected panic attacks, followed by (1) persistent concern or worry about additional panic attacks or their consequences (e.g., losing control, having a heart attack, “going crazy”) or (2) significant maladaptive change in behavior related to the attacks (e.g., behaviors designed to avoid having panic attacks, such as avoidance of exercise or unfamiliar situations).[13] Persons experiencing a panic attack may have tachycardia, chest pain, pounding heartbeats, nausea, dizziness, sweating, or shortness of breath.

Individuals who experience frequent anxiety or have a history of beaing fearful are more likely to have panic disorder. Additional risk factors include childhood physical or sexual abuse, as well as parents with a history of depression, anxiety, or bipolar disorder. There may be a genetic component to panic disorder as well.

Medications such as SSRIs, SNRIs, beta blockers, and benzodiazepines can be used to ease the symptoms and reduce the number of panic attacks, but the primary treatment for panic disorder is psychotherapy. Beta blockers can reduce some of the physical symptoms. Benzodiazepines are strong sedatives and can quickly ease anxiety; because they can cause tolerance and dependence, they are not recommended as a regular therapy. CBT appears to be

the most useful approach for treating women with this disorder.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder is a response to a traumatic event that includes re-experiencing the event with nightmares, flashbacks, or other intrusive thoughts; avoidance of anything associated with the traumatic event and/or emotional numbing; and alterations in arousal such as sleep disturbance, difficulty concentrating, or aggressive behavior.[13] Precipitating events may include mass conflict, a natual disaster, population displacement, combat, sexual violation, serious illness, or life-threatening accident. The person with PTSD has either directly experienced a trauma, witnessed a traumatic event, or learned of a life-threatening event experienced by a close family member.

The diagnosis of PTSD is made when the symptoms cause distress or impairment in normal daily function for at least a month. The diagnostic criteria for PTSD are listed in **Table 8-12**. All of these criteria include significant distress or impairment in social, occupational, or other areas of function. To make a diagnosis of PTSD, the criteria cannot be attributable to direct physiologic effects of substances such as medication, drugs, or alcohol, nor can they be ascribed to another disease or condition.

Table 8-12 **Diagnostic Criteria for Post-Traumatic Stress Disorder**

1. Exposure to actual or threatened death, serious injury, or sexual violation by direct experience of the traumatic event or by witnessing the event affect a significant other, learning of the event occuring to a significant other, or experiencing repeated exposure to traumatic events
2. Presence of one or more of the following symptoms associated with the traumatic event(s), beginning after it occurred: intrusive, disturbing memories; distressing dreams; dissociative reactions; intense psychological distress in response to cues related to the event(s); and marked physiological reactions to reminders of the event(s)
3. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the event(s) occurred, as evidenced by avoidance or efforts to avoid one or more of the following: distressing memories of the event, thoughts or feelings associated with the event, and external reminders of the event
4. Negative alterations in cognition and mood associated with the traumatic event(s), beginning or worsening after the event(s) occurred, as evidenced by two or more of the following: inability to remember an important aspect of the traumatic event(s); persistent and exaggerated negative beliefs or expectations about oneself, others, or the world; persistent, distorted blame of self or others about the cause or consequences of the traumatic event(s); persistent negative emotional state; markedly diminished interest or participation in significant activities; feelings of detachment or estrangement from others; persistent inability to experience positive emotions (e.g., unable to have loving feelings, psychic numbing)
5. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by aggressive or destructive behaviors, hypervigilance, difficulty concentrating, and sleep disturbances

Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders.* 5th ed. Arlington, VA: American Psychiatric Association; 2013.[13]

Some subgroups in the United States have significantly higher prevalence of PTSD than the general population. Notably, women are 2 to 4 times more likely than men to develop PTSD.[75]

Sexual assault is the most frequent trauma leading to PTSD in women. A study of college-age women in 2000 found that approximately 20% to 25% of women in this age group were subjected to sexual assault or attempted sexual assault, leading to a large pool of women at risk for developing PTSD.[76] What we know about the complex relationship between pregnancy, birth, and PTSD is reviewed later in this chapter.

The most common treatments for PTSD are CBT, exposure therapy, and eye-movement desensitization and reprocessing (EMDR) therapy.[77] Psychotherapy employing exposure therapy and CBT has been found to be more effective than pharmacotherapy, although SSRIs are also used as treatment for PTSD. PTSD is often comorbid with depression or substance abuse, and persons with PTSD and substance abuse have more severe symptoms of both disorders.[76] Among the newer therapies for PTSD that appear promising is virual reality exposure therapy, which simulates the traumatic experience. Repeated exposure to the simulation reduces anxiety and fear related to that event.

Many individuals are exposed to traumatic events, yet only a minority develop PTSD. Resilience allows the majority of individuals who experience a traumatic event to recover without any long-lasting mental health disorder.[75] Further research is needed to explore factors that promote resilience.

Treatment of Anxiety Disorders

Both psychotherapy and pharmacotherapy play important roles in the treatment of individuals with any of the anxiety disorders. Like individuals with depression, those persons with anxiety disorders are at an increased risk of committing suicide when compared to the general population. Therefore, the clinician has a responsibility to screen for suicidal ideation in any woman with an anxiety disorder. The effectiveness of pharmacotherapy compared to psychotherapy is similar for individuals with anxiety disorders, and combined treatment has higher response rates than monotherapy.[78,79] The one exception is PTSD, for which psychotherapy appears to be the most effective form of therapy.

Cognitive-behavoral therapy, mindfulness-based cognitive therapy, exposure-based therapy, and therapist-supported Internet-based CBT have all been found to be effective for treatment of women with anxiety.[67,80,81] The same benefits seen with collaborative care models that employ a specially trained case manager for the treatment of women with depression apply to the treatment of women with anxiety.[82] Individuals with anxiety disorders are more likely to prefer CBT than medication alone.[82] It is unclear whether combining psychotherapy and medication offers the same benefit for anxiety as it does for depression.

When pharmacotherapy is indicated, SSRIs are the recommended first-line pharmacotherapy for GAD, generalized social anxiety, and PTSD.[78,83] The benefits of the SSRIs in the treatment of women with anxiety disorders are the same as the benefits for women with depression. These agents have been well studied, are safe and effective, and are well tolerated. As with depression, it may take up to 4 weeks for an individual to show a response; if no clinical response occurs by 6 weeks of treatment, there is a low likelihood of eventual reponse.[84] The same cautions that are decribed in the initiation of SSRIs in the area of depression apply for

anxiety. The woman should be counseled that she may experience a transient increased nervousness in the first few days of treatment, but that this usually dissipates within 2 weeks. The dosages for the treament of anxiety disorders are similar to those for depression.

Benzodiazepines, usually clonazepam (Klonopin) or lorazepam (Ativan), may be useful for short-term use by women with significant impairment while waiting for the therapeutic effect of an SSRI.[85] These medications may also be useful for the episodic treatment of individuals with panic disorder. Benzodiazepines can be highly addictive, cause drowsiness, may aggravate depression, and should be used with caution with older adults. The risk of depression is higher in individuals who have other dependencies.[86] These risks must be balanced against the benefits that benzodiazepines can offer with short-term or intermittent use.

Mental Health Disturbances Related to the Menstrual Cycle

Mental health disturbances related to the menstrual cycle are categorized into "core" and "variant" groups (**Table 8-13**).[13,87-90] The core premenstrual disorders include premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD). Approximately 20% to 30% of menstruating women have PMS, and 1.2% to 6.4% have PMDD, which is a severe form of PMS.[87,89] Variant premenstrual disorders include those not associated with a regular ovulatory cycle.

Table 8-13 Classification of Premenstrual Disorders: Consensus Criteria of the International Society for Premenstrual Disorders, 2008[a]

Definition	Characteristics
Core Premenstrual Disorders	
PMS	Multiple symptoms appear only during the luteal phase of an ovulatory cycle and are relieved within 4 days of the onset of menses without recurrence until the approximate time of ovulation. Must not be an exacerbation of another condition. Symptoms are severe enough to interfere with daily function and cause significant distress. Affective symptoms include angry outbursts, anxiety, depression, irritability, confusion, and social withdrawal. Somatic symptoms include abdominal bloating, breast tenderness, headache, joint or muscle pain, extremity swelling, and weight gain.
PMDD	Classified separately from PMS based on severe psychological symptoms that occur during the luteal phase and remit entirely during the rest of the menstrual cycle.[b] • At least 5 symptoms are present in the final week before menses. They improve within a few days of the onset of menses, and become minimal or absent in the week after menses. • One or more of the following symptoms must be present: marked affective lability, marked irritability, marked depressed mood, and marked anxiety or tension. • One or more of the following must be present to reach the total of five symptoms: decreased interest in usual activities, difficulty concentrating, lethargy, change in appetite, hypersomnia or insomnia, sense of being overwhelmed, and physical symptoms such as breast tenderness or abdominal bloating. • Symptoms are associated with significant distress and not an exacerbation of another disorder or attributable to the effects of a substance or medication.
Variant Premenstrual Disorders	
Premenstrual exacerbation	Luteal-phase exacerbation of another condition such as depression, diabetes, migraine, epilepsy, or asthma
Nonovulatory premenstrual disorders	Symptoms result from ovarian activity other than ovulation
Progesterone-induced premenstrual disorders	Women receiving exogenous progestogens may develop PMS symptoms
Premenstrual disorders without	Symptoms arise from continuous ovarian activity, although menstruation is suppressed

menstruation

Abbreviations: PMDD, premenstrual dysphoric disorder; PMS, premenstrual syndrome.

[a] Diagnosis is based on structured interview, self-report, and prospective recording of at least two menstrual cycles.

[b] See *DSM-5* for a full description of the diagnostic criteria.

Based on American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013[13]; O'Brien PMS, Bäckström T, Brown C, et al. Towards a consensus on diagnostic criteria, measurement and trial design of the premenstrual disorders: the ISPMD Montreal consensus. *Arch Womens Ment Health.* 2011;14(1):13-21[88]; Ismaili E, Walsh S, O'Brien PMS, et al. Fourth consensus of the International Society for Premenstrual Disorders (ISPMD): auditable standard for diagnosis and management of premenstrual disorder. *Arch Womens Ment Health*. 2016;19:953-958.[90]

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

The core premenstrual disorders are characterized by timing of somatic and/or psychological symptoms that occur during all or part of the 2-week premenstrual phase and resolve during or after menses starts in women with ovulatory cycles. Women with one of these disorders have a symptom-free interval between menses and ovulation.

The etiology of premenstrual disorders is poorly understood, but cyclic changes in progesterone and estrogen levels appear to trigger the symptoms. Premenstrual disorders share features associated with anxiety and depression, which have been linked to serotonergic dysregulation. It is thought that changes in estrogen and progesterone levels affect serotonin and dopamine levels, although other neurotransmitters may also be involved.[87,88,91–93] Recent research suggests PMDD may be the result of extreme neurologic sensitivity to normal hormone variations.[92] Genetic vulnerability probably also plays a role in determining which women experience PMDD.[93]

Diagnosis of PMS or PMDD is based on nature and number of symptoms, cyclicity, severity, and chronicity of symptoms.[94-96] The Daily Record of Severity of Problems, an instrument validated by Endicott et al., is the most widely used daily symptom scale because it measures all 11 of the *DSM-5* symptoms of PMDD.[95] This record can be printed and used by women to record their symptoms over a few months.

PMDD is a psychiatric illness that affects approximately 5% of women during their fertile years.[89] It is the most severe, yet least common, of the menstrual disorders. The most frequent and disabling symptoms of PMDD are extreme irritability and mood lability. Disordered sleep (either insomnia or hypersomnia) and extreme changes in tension or energy are also reported. Confusion and alterations in mental status are prominent in PMDD, which can result in women being unable to work. Women experiencing PMDD may have difficulty with relationships on the days that they are symptomatic. They may also experience comorbidity of their PMDD with other mood or anxiety disorders such as MDD, bipolar disorder, or OCD.[89]

Treatments for PMS and PMDD

Treatments for PMS and PMDD include: (1) nonpharmacologic approaches such as diet, exercise and psychotherapy; (2) SSRIs; (3) hormonal agonists and antagonists; and (4)

vitamins and botanical products.[87]

Nonpharmacologic approaches may help stabilize mood and relieve physical symptoms, but there is little evidence to support these approaches as monotherapy. A diet that includes complex carbohydrates, consumed during the luteal phase, may be helpful, as this type of diet boosts the amount of serotonin present in neural synapses.[87] CBT can help women manage their symptoms.

The strongest evidence for effective treatment of women with PMDD involves boosting neurotransmitter presence or suppressing ovulation. Within the neurotransmitter approach, the SSRIs are the most-studied antidepressants used as pharmacotherapy for women with PMDD. All of the SSRIs appear to be equally effective, however, and both continuous and intermittent dosing regimens are used. A moderate dose may be effective and well tolerated.[97] The action of SSRIs for PMDD differs from their action for other psychiatric conditions in two basic ways:

- Relief of symptoms occurs in the first cycle of use. Ordinarily, SSRIs require up to 2 months before reaching full effectiveness.
- The SSRI is effective when taken only at intervals, rather than every day. Withdrawal symptoms do not appear when the SSRI is discontinued after several days or a week of use.

The second strategy aims to create a steady hormonal state, without the cyclic fluctuations that appear to trigger the neurologic cascade resulting in PMDD. Hormonal contraceptives can suppress ovulation and are widely acceptable to women who do not want to become pregnant. Oral contraceptives containing drospirenone (e.g., Yaz, Yasmin) have been the most specifically studied for their effectiveness in treating PMDD and PMS.[98] Women who use drospirenone-containing contraceptives have an increased risk for deep vein thrombosis, which must be taken into consideration before prescribing these agents. Fluctuation of hormone levels can be further minimized by using long-cycle or continuous-dosing regimens.[99] Long-term suppression of ovulation, using leuprolide acetate (Lupron, Lupron Depot) plus add-back estrogen, may be effective.[100]

Premenstrual Exacerbation of Psychiatric Conditions

Much more common than PMDD is the worsening of other psychiatric conditions that follows the menstrual cycle. Mood and anxiety disorders are more prevalent in the menstruating population than is PMDD. Because women themselves often feel confused about the causes of their distress, it is important to carefully identify menstrual-related symptoms so as to correctly diagnose and address the underlying condition. Reviewing the woman's daily symptom diary can be key to distinguishing between PMDD or another psychiatric diagnosis.

Fortunately, the PMDD treatment strategies can help women with other conditions. Hormonal contraceptives have been used as an adjunct treatment for underlying depression that worsens prior to menses,[101] and the midwife who is familiar with the range of products and dosing regimens can fine-tune treatment for an individual woman's needs in consultation with

the woman’s psychiatric provider.

Women with psychiatric illness may have difficulty making sound decisions in their own best interest. Depression, for example, can slow cognition and impair memory; anxiety can be a force for confusion and distraction. Women with bipolar illness may have difficulty with impulse control and irritability. In working with these women to minimize their symptoms across the menstrual cycle, midwives need to remain mindful of the possible impaired decision making that mental illness can cause in some persons. It may be necessary to consult with the woman’s mental health clinicians to determine the most effective plan of care. In some situations, inclusion of significant others or family members in making a plan can be helpful as well.[102]

Perinatal Mental Health

Childbearing is a time of profound change. An increasingly robust body of literature links the mental health of the mother with the optimal outcome of the pregnancy and birth, and with the cognitive and social development of the offspring.[103] Women with mental health disorders may struggle to negotiate the demands of parenthood, and when they falter, their children—and other family members—may be affected as well.*104* Women with a history of depression who are not aware of being depressed after childbirth may be less engaged with their infants than women without a history of depression. This lack of a close bond may, in turn, affect the infant's neurochemical and neuroendocrine development.[105]

Women are more likely to be diagnosed with a psychiatric disorder during their fertile years than at any other time in their lives. In addition, women are most vulnerable to psychiatric illness while they are pregnant or during the postpartum period.[106]

Mental Health Disorders During Pregnancy

The prevalence of various psychiatric conditions during pregnancy mirrors their prevalence in the general population. Mood and anxiety disorders predominate in women across sociodemographic and age groups; they are also the most commonly diagnosed psychiatric conditions during pregnancy.[3] Approximately 10% to 20% of women will experience minor or major depression during pregnancy.[107] Notably, this incidence may be much higher in some populations that are traditionally not included in epidemiologic surveys. For example, approximately one in three women who migrate from low- and middle-income countries have minor or major depression during pregnancy.[107,108]

Untreated depression and anxiety disorders can adversely affect the course and outcome of pregnancy.[109-112] Untreated depression or anxiety during pregnancy is associated with substance abuse, smoking, and other behaviors that can independently affect pregnancy outcomes. Women with untreated depression have increased risks of preterm birth and fetal growth restriction. In addition, these women are at increased risk for postpartum depression and their children are at increased risk for developmental and behavioral problems.[109-112] The strongest predictors of depression during the postpartum period can be identified during pregnancy, including depression or anxiety during pregnancy, stressful life effects and poor social support during pregnancy, and a history of depression at any other time in a woman's life.

Screening for Depression and Anxiety During Pregnancy

The U.S. Preventive Services Task Force, the American College of Obstetricians and Gynecologists, and the American College of Nurse-Midwives all recommend regularly screening women for perinatal depression.[113-115] In addition, many states mandate that providers screen for depression during pregnancy. Any woman who has risks for or symptoms of depression should be screened two or three times during pregnancy, and all women should be screened at least once. The Council on Patient Safety in Women's Health Care has developed an interdisciplinary patient safety bundle to address maternal mental health that addresses readiness, recognition, prevention strategies, response, and reporting systems for both clinical settings and for evaluating individual women.[115] The list of resources at the end of this chapter has more information about accessing this patient safety bundle.

Symptoms of prenatal depression include crying, weepiness, sleep problems, fatigue, appetite disturbances, anhedonia, anxiety, problems with fetal attachment, and irritability. Because many of these symptoms can also be normal transient problems during pregnancy, formal screening to differentiate normal symptoms from major or minor depression is essential.

General screening for perinatal mental health disorders should also include an assessment for thyroid abnormalities that can trigger psychiatric symptoms. Elevations in thyroid-stimulating hormone (TSH), free T_4, and thyroid antibodies have been associated with depression during pregnancy and postpartum. A study by Sylvén et al. found that an abnormal TSH level at the time of birth was associated with an elevated risk for postpartum depression

at 6 months following birth (OR, 11.30; 95% CI, 1.93-66.11).[116]

Many instruments are available for screening during pregnancy (**Table 8-14**).[113-119] The PHQ-9 and the GAD-2[72] are quick, cost-effective ways to identify those at risk, but their inclusion of constitutional symptoms that are common in pregnancy reduces their specificity. The Beck Depression Inventory has been validated for use during pregnancy but is copyrighted and requires a fee for its use. All of these scales have been translated and validated for many different languages.

Table 8-14 Screening Tools for Perinatal Depression

Screening Tool	Methods of Administration	Time to Complete (min)	Sensitivity (%)	Specificity (%)
Beck Depression Inventory II	21 items self-administered or interview	5–10	56–57	97–100
Center for Epidemiologic Studies Depression Scale	20 items self-administered	5–10	60	92
Edinburgh Postnatal Depression Scale	10 items self-administered	< 5	59–100	49–100
Patient Health Questionnaire-9	9 items self-administered	< 5	75	95
Postpartum Depression Screening Scale	35 items self-administered	5–10	91–94	72–98
Zung Self-Rating Depression Scale	20 items self-administered	5–10	45–89	77–88

Based on American College of Obstetricians and Gynecologists. Committee Opinion No. 630: screening for perinatal depression. *Obstet Gynecol*. 2015;125:1268-1271[113]; Gaynes BN, Gavin N, Meltzer-Brody S, Lohr KN, Swinson T, Gartlehner G, Brody S, Miller WC. *Perinatal Depression: Prevalence, Screening Accuracy, and Screening Outcomes. Evidence Report/Technology Assessment No. 119*. AHRQ Publication No. 05- E006-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005.[118]

Originally developed in the United Kingdom by Cox et al., the Edinburgh Postnatal Depression Scale (EPDS) has been validated for use both during the pregnancy and postpartum in a wide variety of populations and is the most commonly used screening tool (**Table 8-15**).[113,118] It consists of a self-report series of 10 questions that takes approximately 5 minutes to complete. It is freely available to any who want to use it. The EPDS has been validated for many populations and several languages, and it has a higher level of accuracy for women in low-resource settings compared to other tools. However, some translations of this tool have not been tested for cultural sensitivity or comprehensibility in different languages, and it may not be as accurate when used by women whose native language is not English. The EPDS, which also assesses for anxiety, can be used to monitor progress in women over the course of pregnancy and postpartum (**Figure 8-5**).[119]

Table 8-15	Edinburgh Postnatal Depression Scale
1. I have been able to laugh and see the funny side of things.	**0** As much as I always could **1** Not quite so much now **2** Definitely not so much now

	3 Not at all
2. I have looked forward with enjoyment to things.	**0** As much as I ever did **1** Rather less than I used to **2** Definitely less than I used to **3** Hardly at all
3. I have blamed myself unnecessarily when things went wrong.	**3** Yes, most of the time **2** Yes, some of the time **1** Not very often **0** No, never
4. I have been anxious or worried for no good reason.	**0** No, not at all **1** Hardly ever **2** Yes, sometimes **3** Yes, very often
5. I have felt scared or panicky for no good reason.	**3** Yes, quite a lot **2** Yes, sometimes **1** No, not much **0** No, not at all
6. Things have been getting on top of me.	**3** Yes, most of the time I haven't been able to cope at all **2** Yes, sometimes I haven't been coping as well as usual **1** No, most of the time I have coped quite well **0** No, I have been coping as well as ever
7. I have been so unhappy that I have had difficulty sleeping.	**3** Yes, most of the time **2** Yes, quite often **1** Not very often **0** No, not at all
8. I have felt sad or miserable.	**3** Yes, most of the time **2** Yes, quite often **1** Not very often **0** No, not at all
9. I have been so unhappy that I have been crying.	**3** Yes, most of the time **2** Yes, quite often **1** Only occasionally **0** No, never
10. The thought of harming myself has occurred to me.	**3** Yes, quite often **2** Sometimes **1** Hardly ever **0** Never

The scores for each item are totaled. Scores greater than 12 require evaluation and possible referral to a mental health specialist. Scores between 10 and 12 indicate the presence of symptoms of distress. The test should be repeated in 1 to 2 weeks and referral considered. Scores between 0 and 9 indicate that any symptoms of distress may be short-lived and not likely to interfere with day-to-day function. If they persist more than 1 to 2 weeks, further evaluation is recommended.

of the 10-item Edinburgh Postnatal Depression Scale. *Br J Psychiatry.* 1987;150:782-786.[117]

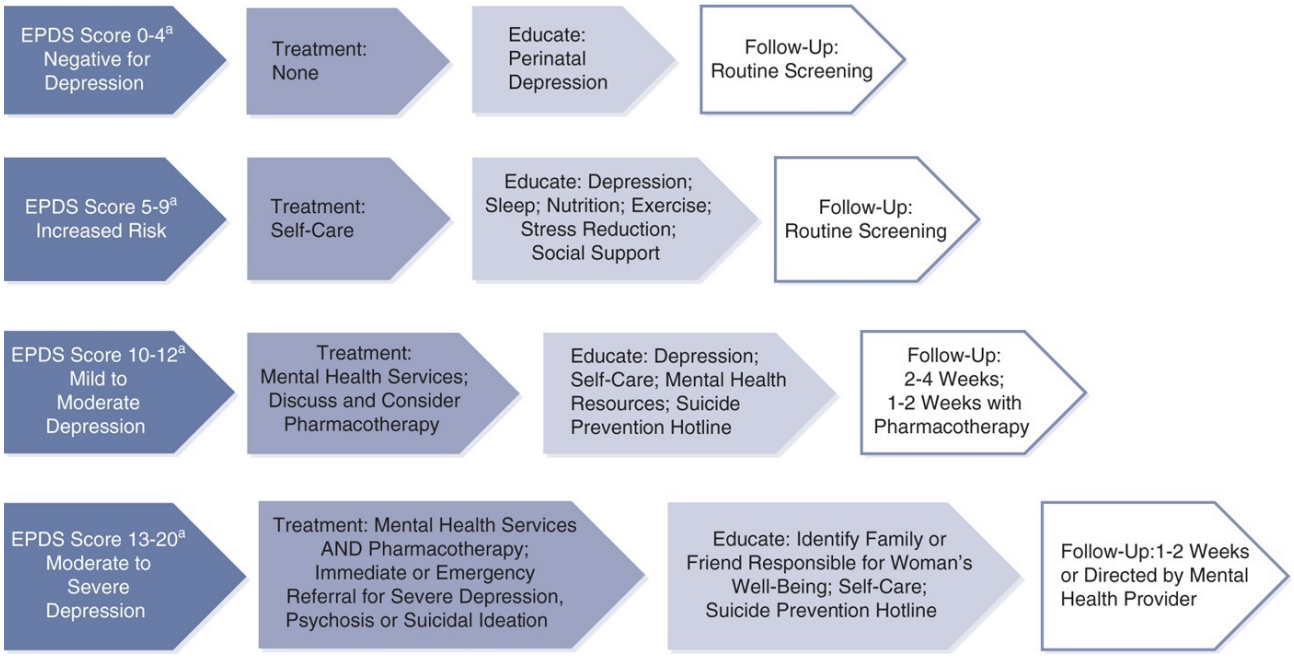

Figure 8-5 Screening and treatment algorithm for perinatal depression.

Abbreviation: EPDS, Edinburgh Postnatal Depression Scale.

a Regardless of EPDS score, a response indicating thoughts of harming self or others should be addressed directly

Reproduced with permission from Latendresse G, Deneris A. Selective serotonin reuptake inhibitors as first line antidepressent therapy for perinatal depression. *J Midwifery Womens Health.* 2017; 62(3):317-328.[119] © 2017, with permission from Wiley.

Three points must be kept in mind when using one of these screening tools:

- The screening tools detect an increased risk for depression, but do not *diagnose* depression. The diagnosis is made via a more in-depth assessment by a mental health professional.
- Any answer that indicates the woman is severely depressed or may have suicidal ideation must be explored further and may be a medical emergency requiring immediate evaluation. Thus, screening should be done within a system that provides access to mental health providers.
- It is extremely important to distinguish unipolar depressive illness from bipolar depression, as the treatment and prognosis for each of these disorders are quite different, and because use of an antidepressant medication may exacerbate bipolar illness.[115]

Psychiatric illnesses have a high comorbidity with each other; therefore, when one disorder is identified in a pregnant woman, the possibility that more than one condition may be present should be considered. A thorough history will reveal previous episodes of mental illness experienced by the pregnant woman or members of her family. Whenever possible, contact the mental health professionals who have cared for the woman in the past to confirm her account, as mental disorders may cloud the memory. Women who have discontinued their psychotropic

medication before becoming pregnant should be counseled about the significant risk of relapse during pregnancy; as many as 68% of women with major depression[106] and 70% of women with bipolar disorder who discontinue psychotropic medication will relapse during pregnancy.[103,120]

Risk factors such as onset of depression before age 18 years, individual or family history of suicide attempts, and multiple unsuccessful trials of antidepressant medications often predict a bipolar origin of depression. Even if a woman with bipolar disorder has been stable for some years before pregnancy, she is at risk for relapse of illness during her pregnancy. Aggressive treatment of women with bipolar illness and protection of sleep are key elements in preventing mania and psychosis postpartum; such measures can reduce but not eliminate these risks.[121]

Anxiety disorders can also develop de novo or relapse during pregnancy, and it can be difficult to differentiate the normal parental anxieties from disabling illness. GAD appears to have a prevalence of approximately 7% among pregnant women, but the risk may be greater for women with a history of child abuse, poor social support, or previous episodes of anxiety.[122] Obsessive–compulsive symptoms can be present during pregnancy, tend to become worse postpartum, and are highly comorbid with depressive illness.[123]

Pharmacotherapy for Perinatal Depression

A mental health disorder that appears or recurs during pregnancy requires collaborative management by the woman and her mental health clinicians. Women who have a history of major mental illness, such as bipolar disorder, eating disorders, and PTSD, need to be comanaged with a mental health clinician who helps to develop the plan of care. The combination of psychotherapy with psychotropic medication has been shown to have higher remission and lower relapse rates than either type of treatment alone.

Midwives who are knowledgeable about both depression and the pharmacology of the medications used to treat depression may prescribe these medications. Safe practice requires that the midwife has access to mental health resources and can provide continuity of care, and that the woman does not have symptoms indicating the need for care by a mental health professional, such as suicidal ideation or a history of hospitalization. Many of the SSRIs are associated with significant drug–drug interactions, so it is important that a prescribing midwife obtain a history of all medications and other products the woman is taking, and be aware of any potential interactions. Women who have multiple comorbidities are best managed by a mental health specialist.

The choice to use medication during pregnancy is complex. Randomized controlled trials (RCTs) are impossible to conduct with pregnant women as participants, leaving clinicians to consider the conflicting findings of many observational, anecdotal, retrospective, and open trials of the various antidepressant medications. In addition, many studies conflate possible medication side effects. Thus, to date, no absolute rules for prescribing antidepressants during pregnancy have emerged. Each woman needs to make an individual choice based on her diagnosis, the likely progression of her illness, and the results of shared decision making. Information provided as part of shared decision making will include possible adverse effects over the course of the pregnancy, including risks of no treatment, fetal effects, newborn effects,

and neurobehavioral effects on the child. The risks of not treating depression must be balanced against possible risks associated with the medication. For example, infants whose mothers had perinatal depression have higher cortisol levels than infants whose mothers were not depressed; these elevations continue through adolescence. Treatment of women with depression during pregnancy appears to normalize this elevation.[124]

Potential Risks Associated with SSRI Use During Pregnancy

Approximately 7% to 13% of women in the United States use an antidepressent during pregnancy.[125] SSRIs are the most commonly used pharmacotherapy for treating perinatal depression and as their use increases, information about positive and adverse effects is rapidly changing. Studies that have found associations between antidepressents and perinatal outcomes have many methodologic challenges, including small sample sizes, recall bias, self-reported data, and outcome measures that are too rare to detect. Thus, large epidemiologic population-based observational studies are the current best resource for detecting an association between medication taken during pregnancy and an adverse outcome, and these studies are not able to conclusively determine an etiologic relationship. That said, **Table 8-16** summarizes the known risks associated with SSRI use during pregnancy and lactation.[119–134]

Table 8-16 Risk Summary for SSRIs Used During Pregnancy and Breastfeeding

Risk	Description
Spontaneous abortion	Well-controlled studies indicate no increase in risk.
Congenital malformations	Well-controlled studies indicate no increase in risk for major congenital malformations in association with SSRIs as a class of drugs.
Congenital cardiac malformations	Well-controlled studies indicate increased risk is associated only with paroxetine (Paxil) (OR, 1.28; 95% CI, 1.11–1.47). May warrant echocardiogram for exposed fetuses.
Preterm birth	Depression and SSRIs are both consistently associated with an increased risk for preterm birth, but it is not clear if this increase is related to depression or to the medication.
Low birth weight	Most well-controlled studies indicate no increase in risk. Possible risk (OR, 2.26; 95% CI, 1.31–3.91).
Postpartum hemorrhage	Controlled studies indicate possible increased risk for postpartum hemorrhage (RR, 1.53; 95% CI, 1.25–1.86) and severe postpartum hemorrhage (RR, 1.84; 95% CI, 1.39–2.44).
Persistent pulmonary hypertension of the newborn	Controlled studies indicate low absolute risk increase (OR, 1.28; 95% CI, 1.01–1.64).
NAS	Controlled studies indicate substantially increased risk for NAS (OR, 5.07; 95% CI, 3.25–7.90). This is more common with fluoxetine (Prozac) and paroxetine (Paxil). Reports of mild NAS in 22% of exposed neonates, hypoglycemia in 19%, and severe NAS in 3% of newborns. May be attributed to SSRI withdrawal or serotonin syndrome. Clinical monitoring of exposed neonates recommended.
Autism spectrum disorders	Conflicting reports. No well-controlled studies. Possibly increased risk (OR, 1.81; 95% CI, 1.47–2.24). Association may be due to psychiatric disorder rather than SSRI exposure.

Effects on breastfeeding infant	Very little evidence of adverse effects on breastfeeding infants. Some case reports of newborn drowsiness, fussiness, irritability, feeding difficulty, hypertonia, hypotonia, weight loss, colic, and withdrawal syndrome with breastfeeding cessation.

Abbreviations: CI, confidence interval; NAS, neonatal adaptation syndrome; OR, odds ratio; RR, relative risk; SSRI, selective serotonin reuptake inhibitor.

Modified with permission from Latendresse G, Deneris A. Selective serotonin reuptake inhibitors as first line antidepressant therapy for perinatal depression. *J Midwifery Womens Health.* 2017;62(3):317-328.[119] © 2017, with permission from Wiley.

Reputable evidence-based online resources are available to clinicians and women to help guide decisions about medication use during pregnancy and breastfeeding. Some of these resources are listed in the Resources section at the end of this chapter.

Although there is no evidence that some medications work better during pregnancy than other agents do, recommendations for selecting SSRIs for use in pregnant women are evolving. It is generally recommended that treatment be initiated with sertraline (Zoloft) or citalopram (Celexa). Fluoxetine (Prozac) is not considered a first-line choice due to its long half-life. Note that citalopram is associated with elevated serum levels in breastfed infants.

In general, dosing regimens for pregnant women are similar to those for nonpregnant women, albeit with these two considerations:

- Blood volume expansion begins early in pregnancy, and hemodilution usually necessitates progressively higher doses of medication across the pregnancy to achieve a stable clinical effect.[135]
- Because of shifting gestational hormones, metabolism and excretion of medications can vary across pregnancy. This can alter the effectiveness of medication, and is another reason why monitoring psychiatric symptoms throughout the pregnancy is important.

Complementary Therapies for Perinatal Depression

Some women who opt not to participate in therapy or take psychotropic medications consider complementary therapies to help manage their perinatal depression. Omega-3 fatty acids, especially eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have well-established health benefits for pregnancy and infant development. They have also been found to be beneficial in the treatment of individuals with major depression, primarily as adjunct therapy rather than as monotherapy.[37] Results of studies in the treatment of antenatal depression have been mixed. Omega-3 supplements are well tolerated, and psychiatrists at the University of Massachusetts Medical School recommend 1 g EPA plus DHA daily for pregnant women with depression.[37]

S-Adenosyl-methionine (SAMe) also has an antidepressant effect. Although it has been investigated as a treatment for intrahepatic cholestasis of pregnancy, and was not associated with adverse effect, it has not been well studied for use in the management of depression during pregnancy.[37]

St. John's wort (*Hypericum perforatum*) is an herbal dietary supplement that is used in the treatment of individuals with depression. Studies of its effectiveness in reducing depression

have yielded varied results; one meta-analysis done in Germany found that St. John's wort was comparabe to SSRIs, and better for a subgroup of individuals with mild to moderate depression.[136] St. John's wort induces the cytochrome P450 system, and has multiple drug interactions. There have been only limited studies of its use during pregnancy or breastfeeding, so it is not recommended for use in the perinatal period.[37]

Bright light therapy is a safe and effective treatment for pregnant and breastfeeding women once bipolar disorder has been ruled out. Moderate exercise for 30 minutes per day reduces depressive symptoms, and has been recommended by the American College of Obstetricians and Gynecologists for general well-being during pregnancy. Massage therapy can also be recommended as an adjunct therapy. Acupunture therapy may have a benefit in some women.[37]

Post-Traumatic Stress Disorder During the Perinatal Period

The perinatal period can be especially difficult for women who have a history of physical, emotional, or sexual abuse. Women who have PTSD may experience pregnancy, labor, or birth as traumatic. Women who do not have symptoms of PTSD prior to pregnancy may develop this condition when they experience physical vulnerability during pregnancy, and intimate contact during vaginal examinations, labor, and birth. One in five women has a history of a childhood maltreatment.[137] Midwives need to understand the sequelae of sexual abuse in particular, so as to offer these women safe therapeutic care.[137]

Women who have experienced childhood trauma, sexual abuse, depression, or PTSD preceding the pregnancy are at increased risk for PTSD during the perinatal period.[138] The reported incidence of PTSD during pregnancy ranges from 3% in high-resource settings to more than 14% in low-resource settings.[137] Anxiety sensitivity reflects a tendency to respond fearfully to anxiety itself (as opposed to just responding to stressors) and has been found to increase vulnerability to PTSD.[139]

Depression, anxiety, and fear of childbirth during the pregnancy are also predictors of postpartum PTSD. The traumatic stressor for postpartum PTSD is birth trauma, "an event occurring during the labor and delivery process that involves actual or threatened serious injury or death to the mother or her infant."[140] Thus, it is the *perception* of risk that predisposes women to PTSD rather than the *absolute* risk. For example, a woman may perceive her birth as traumatic depsite the perception by the clinicians that everything was routine.[140]

Not surprisingly, emergency cesarean birth and instrumental birth are associated with PTSD—but so are negative emotions such as a negative experience of labor and birth and a loss of control. A sense of not receiving adequate support—especially from care providers, but also from a partner—can contribute to the risk for postpartum PTSD.[138]

Being alert to risk factors for PTSD and signs of crisis, such as withdrawal, signs of acute distress during labor, or dissociative behaviors, may allow midwives to identify women at high risk for PTSD, and provide the opportunity to offer trauma-informed care during pregnancy,[137] provide more intensive support and communication during labor, and make an early referral if indicated at any time in the perinatal period. Limited research has addressed treatment for PTSD specifically following childbirth; those studies that have been conducted

suggest that many of the same therapies that are employed for PTSD in general have a benefit for women with postpartum PTSD. These include counseling, cognitive-behavioral therapy, and eye-movement desensitization and reprocessing.

Postpartum Mood Disorders

Changes in mood are experienced by a majority of women after childbirth. Estrogen levels, which have a significant influence in neurotransmitter systems, decrease during the postpartum period. In addition, lower serotonergic activity following birth has been noted. Downregulation of the hypothalamic–pituitary–adrenal axis following birth may also contribute to increased vulnerability to depression.[115] While these physiologic changes do not lead to depression in all postpartum women, when they are coupled with a history of prior depression or bipolar disorder, a genetic predisposition, inadequate social support, and multiple stressors, it is not surprising that childbirth can present a challenge to a woman's mental health and well-being. Disturbances in sleep patterns and circadian rhythms are also universal in new mothers. Melatonin release is suppressed by exposure to light when a person would normally be sleeping.[141] Postpartum insomnia may both contribute to and be aggravated by MDD.[142]

A description of and diagnostic criteria for the most common postpartum mood disorders appear in **Table 8-17**.[143]

Table 8-17	Diagnostic Criteria for Postpartum Depression Disorders

Postpartum Blues (Baby Blues)
Affects 80% of new mothers Onset: first 7–10 days after birth Peak prevalence: postpartum days 3–5 No specific diagnostic criteria Most common symptom: weepiness Other symptoms: mood lability, feeling overwhelmed, sadness and frustration, fatigue/exhaustion
Postpartum Depression
Affects 10–20% of new mothers Onset: first 2–3 months postpartum Peak prevalence: 2–6 months postpartum Must include depressed mood or anhedonia and any of the following symptoms, which occur nearly every day for at least 2 weeks and are severe enough to impede function: 1. Sleep disorder (insomnia or hypersomnia) a. Must be evaluated in the context of the expected sleep pattern with a newborn b. Can the woman sleep when her infant is asleep? 2. Interest deficit or a lack of feeling pleasure a. Inability to appreciate infant, not bonding b. Persistent sadness 3. Guilt (worthlessness, hopelessness, regret) a. More common than feeling sad b. Feeling inadequate as a mother 4. Fatigue or loss of energy nearly every day a. Feeling of being overwhelmed, unable to cope

5. Concentration deficit
    a. Persistent difficulty with normal daily tasks
    b. Difficulty remembering things
6. Appetite disorder (increased or decreased)
    a. Is the woman drinking enough and urinating regularly based on normal postpartum physiology?
7. Psychomotor retardation or agitation
    a. Unable to get out of bed or go to sleep
    b. Loss of interest in caring for oneself
    c. Obsessive thoughts of harm to the infant
8. Suicidality (recurrent thoughts of death)
    a. Thoughts of harming oneself
    b. Do you wish you could go to sleep and not wake up? (passive suicidal ideation)
    c. Do you think about ways to kill yourself? (active suicidal ideation)

Postpartum Psychosis
Affects 12 women per 1000 live births
Onset: usually starts within 2 to 4 weeks of birth, but can start as early as 2 to 3 days after birth and often progresses rapidly
Emergency psychiatric condition characterized by symptoms of:
Delusional beliefs, hallucinations, and disordered thinking
"Everything is black or dark"
Feeling of hopelessness
Delusions about the infant
Auditory hallucinations, which can be instructions to harm the infant
Visual hallucinations

Postpartum Blues

Postpartum blues, also known as baby or maternity blues, is the most common mood change, occurring in 50% to 75% of new mothers.[144] The symptoms of crying, anxiety, emotional lability, irritability, and fatigue peak within 2 to 5 days of their onset, but usually do not interfere with functioning.[144,145] Although postpartum blues is usually benign and self-limited, it can be frightening to a woman. If a woman in the early postpartum period calls with concerns about her emotional symptoms, it is prudent to ask the two questions of the PHQ-2 about (1) finding pleasure in things and (2) feeling predominately down, depressed, or hopeless. If the woman reports anhedonia, a more thorough screen for postpartum depression is warranted. Many practices regularly use the Edinburgh Postpartum Depression Scale to screen for postpartum depression, especially for women who report emotional distress.

The primary differences between postpartum blues, postpartum depression, and postpartum psychosis relate to duration and severity of the symptoms. Characteristics to help the clinician

distinguish between these conditions when assessing a woman who reports disordered mood during the postpartum period are listed in **Table 8-18**.

Table 8-18 Common Clinical Features That Distinguish Postpartum Blues and Postpartum Depression[a]

	Characteristics				
Disorder	**Onset**	**Duration**	**Characteristic Symptoms**	**Degree of Disability**	**Suicidal Ideation**
Postpartum blues	7–10 days after birth	Less than 2 weeks	Crying, sad, labile mood	Minimal; cares for infant without problem	Unlikely
Postpartum depression	2 months to 1 year after birth	More than 2 weeks	Anhedonia, sleep disturbance, guilt, feeling of isolation and loneliness	Severe; may have difficulty caring for infant without help	Possibly present
Postpartum psychosis symptoms	First 2–4 weeks after birth	Mean duration: approximately 40 days	Acute onset of psychosis and delusional thoughts	Severe; psychiatric emergency	Likely; may also have thoughts that the infant is being harmed

[a] This list is a selected group of symptoms that can aid a clinician during the initial evaluation of a woman on the phone or in a triage setting.

Once postpartum blues are determined to be the likely cause of symptoms, anticipatory guidance that these mood swings are commonly experienced and usually resolve spontaneously within 10 to 14 days can reassure new mothers that they are not “going crazy.” Women should also be counseled to seek further evaluation if these symptoms do not resolve within 2 weeks following birth, because as many as 1 in 5 women with postpartum blues will develop a major depression.

Postpartum Depression

Postpartum depression (PPD) is a major depressive disorder. PPD affects women of all cultures, ages, incomes, races and ethnicities.The peak onset for postpartum depression is in the second month after childbirth, and the risk for this disorder remains elevated up to 6 months, or even 1 year, following the birth. The point prevalence of MDD and minor depression range from 6.5% to 12.9% through the first postpartum year, and as many as 19.2% of women will have a major depressive episode at some time during the first 3 months postpartum.[146]

Risk factors for PPD are listed in **Table 8-19**. Adolescent mothers have almost twice the risk for PPD compared to adult women.[147] Adolescents are still achieving their normal developmental tasks, and often have unrealistic expectations of motherhood or the demands of parenting. In addition, adolescents are likely to be more socially isolated from their peers than adult mothers.[147] Immigrant women may also have a greater chance of experiencing PPD, depending on the circumstances of their immigration, social and language isolation, and the unavailablity of traditional childbirth rituals.[147]

Table 8-19	Risk Factors for Postpartum Depression
Strong Risk Factors	**Additional Risk Factors**
Anxiety during pregnancy	Biologic vulnerability
Depression during pregnancy	Family history of depression or postpartum depression
Stressful life events during pregnancy	Unplanned pregnancy
Low level of social support: single marital status	Young maternal age
History of depression	Lower socioeconomic status, financial insecurity
Postpartum depression after a prior pregnancy	History of interpersonal violence
	Thyroid dysfunction

When assessing a woman for PPD, it is critical to rule out postpartum bipolar disorder, which can be severe and possibly lead to postpartum psychosis. Asking women the following two questions will assess for bipolar disorder:

- Have you ever had 4 continuous days when you felt so good, high, excited, or "hyper" that other people thought you were not your normal self or that you got into trouble?
- Have you ever had 4 continuous days when you were so irritable that you found yourself shouting at people or starting fights?[145]

Even women who do not meet the criteria for MDD in the postpartum period often experience negative thoughts that are associated with depression symptomatology. In the United Kingdom, Hall and Wittkowski developed a questionnaire of postpartum negative thoughts (PNTQ) through qualitative interviews with 10 postpartum women who were suffering from postpartum depression.[148] They then distributed 354 questionnaires, along with the Edinburgh Postnatal Depression Scale, to potential participants at 42 baby-weight clinics. Of the 185 mothers who returned the questionnaires, 22 women who scored 12 or higher on the EPDS were excluded from the analysis, as the purpose of the study was to assess negative thoughts in women who did not screen positive for depression. Items on the negative thoughts questionnaire were scored as "not at all," "occasionally," "frequently," or "almost always." Three of the items on the questionnaire were experienced either frequently or almost always by more than 15% of participants: "Everything in my life should revolve around my baby" (26.6%), "I must show everyone that I am coping" (19.8%), and "As a mother, everything must be perfect" (15.9%). The feeling that "my baby could die" was experienced either frequently or almost always by 9.5% of participants, and 9.8% responded with the same frequency that "If there is something wrong with my baby, it's my fault." This study, as well as others,[149] shows that depressive symptoms exist in many more women than meet the diagnostic threshold for "postpartum depression."

Effects of Postpartum Depression on the Family

Partners of women with postpartum depression are also at risk for depression.[141] In addition, women who are depressed may be less responsive to their infants and less likely to engage in

face-to-face interactions that would contribute to infant communication skills, such as vocalizing, smiling, imitation, and game-playing, compared to mothers who are not depressed. They also can display less synchrony in their mother–baby interactions. In turn, untreated depression has been associated with impaired child development. Studies have found consistent evidence for the long-term adverse effects of untreated PPD on subsequent childhood development and behavior. Children of mothers with PPD are more likely to have poor cognitive funtioning, disruptive behaviors, and emotional maladjustment.[150] Finally, because many women with PPD were also depressed during the pregnancy, it can be difficult to separate the contribution of prenatal depression from that of postpartum depression.

Screening for Postpartum Depression

The U.S. Preventive Services Task Force and the American College of Obstetricians and Gynecologists recommend regularly screening for depression, including screening in the postpartum period. Several instruments are available to screen for PPD. Whereas the PHQ-9 is gaining favor as a screening tool for depression in the general population, it does not include items that are specific to childbirth.The EPDS, which was developed in the mid-1980s specifically for use in the postpartum period, has been well validated for use both during pregnancy and postpartum.[147] The Postpartum Depression Screening Scale (PDSS) is another instrument developed for use in the postpartum period. It is self-adminstered, and is available as a long form of 35 items or an abbreviated "short" form of 7 items.[151] The PDSS also is well validated, and may be used to evaluate response to treatment in a depressed women.

The EPDS and PDSS both appear to be more accurate in identifying postpartum depression than generic screening instruments for depression such as the CES-D or BDI. A major advantage of the EPDS over the PDSS is the ability to employ the questionnaire free of charge; in contrast, a charge is levied for the PDSS manual and forms.

A positive result on any screen should be followed up with a diagnostic evaluation by a qualified clinician so as to establish an accurate diagnosis. The screening questionnaires do not differentiate between unipolar or bipolar depression, so women identified as being depressed should be evaluated for a history or symptoms of mania or hypomania. A positive response to the questions that assess suicidality (question 9 on the PHQ-9 and question 10 on the EPDS) requires immediate attention by the clinician. The diagnosis of postpartum thyroiditis should be considered for depressed women with or without a history of autoimmune disorders.[152]

The optimal time to screen for PPD is betweeen 2 weeks to 6 months postpartum,[144] as the point prevalence of postpartum depression has bimodal peaks at 2 and 6 months postpartum. Following a 6-week postpartum visit, women are less likely to be in contact with their midwife, so many women who develop PPD may go unrecognized if screening depends on self-recognition or recognition by family or friends. For this reason, it has been recommended that screening for PPD be incorporated into the infant's well-child visits to the pediatric care provider. The American Academy of Pediatrics suggests that pediatricians should have a low threshold of suspician for parental depression, and consider, at a minimum, asking parents the two questions in the PHQ-2.

Prevention of Postpartum Depression

Primary prevention and secondary prevention addressing early detection and intervention are always preferable to dealing with the sequelae of an illness. Identifying a vulnerability to PPD may allow the midwife an opportunity to recommend interventions that may decrease the woman's risk for PPD. Interventions that may help prevent postpartum depression include interprsonal psychotherapy, regular physical activity, improving or developing a social support system, and arranging to obtain sufficient sleep postpartum.[153,154] Many of these behaviors can be fostered prior to or during pregnancy. For example, counseling regarding exercise (especially outdoors), healthy eating, and good sleep habits can be reinforced at each prenatal visit—not just to ensure physical well-being during pregnancy, but also to promote the mother's mental well-being. The CenteringPregnancy model seeks to improve social support and can be associated with less depression at one year postpartum.[155,156] Joining other postpartum support groups may also help women to develop coping skills.

Psychotherapy may help a woman learn to identify and access sources of support from family and friends, thereby avoiding the development of postpartum depression. Women who are at risk for PPD but have a desire to avoid medication may be especially receptive to this advice. If a woman has experienced depression prior to the pregnancy, but opted to discontinue the medication during the pregnancy, her plan of care may be to restart the medication immediately postpartum and continue it for at least 6 months.

Placing the newly born infant skin-to-skin with the mother has been documented to provide many maternal and infant benefits, including more stable physiologic transition, less crying, and more restful sleep.[153] These neonatal adaptations in and of themselves may allow for less maternal stress. In a quasi-experimental study, Bigelow and colleagues evaluated the effects of continuing daily skin-to-skin contact (SSC) throughout the first month. Participants completed self-report depression scales at 1 week, and 1, 2, and 3 months postpartum. Women in the skin-to-skin contact group reported significantly lower scores on both the EPDS and CES-D scales at 1-week and 1-month visits. This benefit attenuated over time, such that there were not clinically or statistically significant differences at 2 or 3 months postpartum.

Treatment for Postpartum Depression

Identifying women with postpartum depression is only half the battle. Helping women to obtain appropriate treatment is also necessary to have the desired impact on the health of mothers and their families. Unfortunately, a minority of mothers who screened positive for depression are referred for treatment, or for follow-through with their care.[149] The primary care provider is in the best position to maintain ongoing contact with the mother to reinforce ongoing treatment. Such follow-up will decrease the chance that the mother falls through the cracks or discontinues treatment before attaining a satisfactory response.

Accumulated data from many studies indicate that pyschotherapy is helpful for women with mild-to-moderate PPD, and women who are breastfeeding may opt to begin treatment with psychotherapy.[115] The evidence most strongly supports the benefits of interpersonal psychotherapy and CBT.[115]

After excluding the diagnosis of bipolar disorder, a midwife may recommend or prescribe antidepressant therapy. The same considerations that make SSRIs the first-line antidepressants for MDD unrelated to childbirth also make them the mainstay for pharmacologic treatment for PPD. Any of the SSRIs listed in **Table 8-8** can be considered for use postpartum. **Figure 8-6** summarizes the guidelines for postpartum antidepressant management.[157] As a rule, women who were treated effectively with an SSRI or SNRI during pregnancy should continue on the same agent. Although the transfer rates for the different drugs vary, in all cases the infant is exposed to less drug during breastfeeding than during pregnancy.[158] When initiating pharmacotherapy for the first time, sertraline or paroxetine may be considered as first-line agents, based on studies of levels in breast milk and reports of side effects in infants.[159] Fluoxetine (Prozac), citalopram (Celexa), and escitalopram (Lexapro) have higher rates of transfer to the breast milk, and are more often associated with infant behavioral side effects.[159]

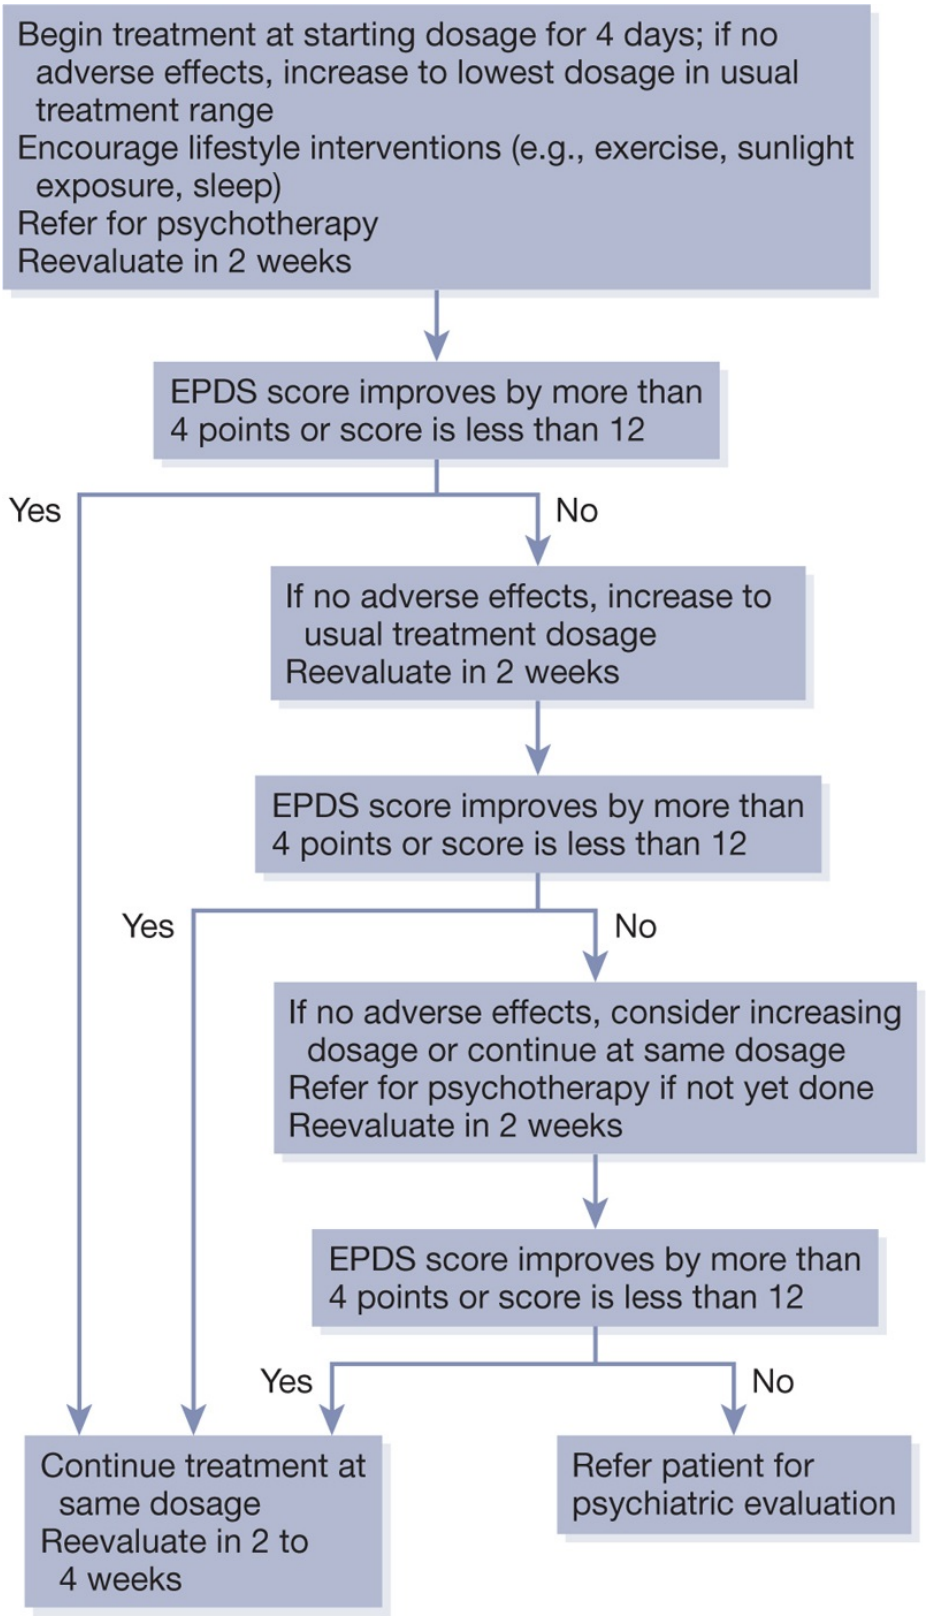

Figure 8-6 Pharmacologic treatment algorithm for postpartum major depression.

Abbreviation: EPDS, Edinburgh Postnatal Depression Scale.

Reproduced with permission from Hirst KP, Moutier CY. Postpartum major depression. *Am Fam Physician.* 2010;82(8):926-933.[157] Copyright © 2010 American Academy of Family Physicians. All Rights Reserved.

A decision to begin an antidepressant is made jointly by the mother and her care provider after a thorough discussion of risks and benefits, including the potential effects of postpartum depression on her infant and any other children. Women who perceive that a treatment decision has been imposed on them are less likely to follow through with the treatment regimen. In the postpartum setting, most women will need higher than the starting doses to achieve a therapeutic effect.

The approach when starting a medication is to begin at a low dose for 5 to 7 days, then titrate doses upward until remission is achieved. Whichever questionnaire was used to initially screen for PPD—whether the EPDS or the PHQ-9—should also be used to monitor response to treatment. Antidepressant therapy should be continued for 6 to 9 months after achieving remission. Counsel the woman that if the medication is stopped abruptly, she will probably experience unpleasant symptoms; instead, the psychotropic agent should be tapered over a period of at least 2 weeks.

Postpartum Bipolar Disorder

Although the general prevalence of bipolar disorder (BPD) is low,[3] there is a significant risk of relapse following birth. In addition, women who experience their first episode of depression in the postpartum period are more likely to have bipolar disorder, with rates varying between 15% and 50%, depending on the diagnostic criteria used.[160]

Women who were diagnosed with BPD prior to pregnancy are best cared for by a multidisciplinary team, including a psychiatrist to manage medications and decrease the chance of a relapse. Between 80% and 100% of women who discontinue their mood stabilizer medication during pregnancy experience a relapse. **Table 8-20** provides some of the essential information to be shared by a midwife with a psychiatrist in a situation of bipolar relapse or possible acute new onset of bipolar disorder postpartum.

Table 8-20 Sample Critical Elements for a Consulation/Transfer Note for a Woman with Bipolar Relapse

Past history and treatment for bipolar disease. Note the success or failure with treatments in the past, especially before pregnancy.
History of pregnancy and details of birth, including the date and the current status of the child.
Signs and symptoms indicating relapse.
Care provided before transfer: procedures and results; laboratory results received or pending; all medications (dosage, route, and time of last dose); response to treatment based on symptoms.
Pregnancy test results if appropriate, based on how many weeks postpartum and sexual activity.
Summary of the rationale for transferring the woman's care to the psychiatrists.
Request for information about the treatment plan for follow-up and/or collaboration.

While the discontinuation of medication is the most important risk factor for relapse, the dramatic hormonal and circadian rhythm alterations that occur after childbirth are also important factors. Women experiencing a bipolar episode postpartum often appear overly euphoric, talkative, and less in need for sleep. Conversely, they may present with the depressive symptoms associated with the disorder. BPD may also present as postpartum

psychosis. Any woman with a history of BPD, or exhibiting signs of either mania or hypomania, should be assessed by a psychiatric clinician.

Postpartum Psychosis

Postpartum psychosis is a rare and life-threatening emergency that requires immediate psychiatric evaluation. Postpartum psychosis occurs in 0.25 to 0.6 women per 1000 live births,[161] and may occur anytime in the first year postpartum. The peak incidence is during the first 4 weeks postpartum; in fact, this mental health disorder may be recognized in the first few days postpartum.[161]

Women with BPD are at a much higher risk for developing postpartum psychosis than other women, and many women who present with postpartum psychosis are ultimately diagnosed with BPD. Autoimmune thyroid disease may also contribute to the development of postpartum psychosis. Women with postpartum psychosis have a 4% to 5% risk of either suicide or infanticide. Treatment of postpartum psychosis often involves hospitalization, lithium therapy, and benzodiazepines to promote sleep.

Conclusion

Millions of women develop mental health disorders in the United States, and these conditions are likely to affect the well-being of both the woman and her family. For some women with mental health disorders, the midwife may be the first—and in some cases, the only—healthcare provider available. As primary care providers, midwives are, at a minimum, responsible for appropriate screening and referral for women at risk for mental health conditions. A system of universal screening can help identify those individuals with mental health concerns, and determine who can be treated safely within a primary care setting and who should be referred for more specialized treatment. With psychiatric consultation and collaboration midwives can provide first-line treatment for many women.

Psychopharmacology is an important component of treatment of mental health disorders. With careful screening, counseling, follow-up, and potential referral, this approach to treatment can be within the scope of midwifery practice. As when prescribing any medication regimen, it is essential that the midwife be familiar with psychotropic medications.

Women's susceptability to mental health disorders is influenced by their life stage and hormonal status. Pregnancy and the puerperium are times characterized by dramatic hormonal shifts, which when compounded with the stresses of becoming a parent can place a woman at increased risk for mood and anxiety disorders. Early identification and treatment can decrease long-term morbidity, but the potential effects of medications on the fetus and nursing newborn must also be considered.

CHAPTER

9

Pharmacotherapeutics

Introduction

Pharmacology is derived from the Greek word *pharmakon*, which means “medicine or poison.” Most sources define pharmacology more precisely as the study of how drugs interact with a living organism to produce a change in physiologic function. Any agent, substance, or medication that is used for medicinal purposes is considered a pharmaceutical. Although midwives may use a wide repertoire of nonpharmaceutical techniques, pharmacologic treatments are indicated for some conditions and situations. Certified nurse-midwives and certified midwives have varying degrees of prescriptive authority in most states within the United States.[1] One of the greatest challenges in clinical practice is maintaining current knowledge about drug indications, doses, side effects, and contraindications, and prescriptive authority.

In the United States, the U.S. Food and Drug Administration (FDA) is the regulatory agency charged with ensuring that drugs, biologic products, medical devices, the national food supply, cosmetics, and products that emit radiation are safe, effective, and secure for consumer use. Other governmental bodies that have some involvement with drugs include the Centers for Disease Control and Prevention (CDC), which publishes recommendations for treatments of disorders and diseases; the Drug Enforcement Administration (DEA), which regulates controlled substances; the Federal Communications Commission (FCC), which regulates advertising of over-the-counter drugs; and state governments, which control prescriptive authority for providers, including midwives.

Most adults in the United States take at least one medication, and many take multiple pharmaceuticals daily. The extensive use of drugs is related to several factors: the increase in their availability; the public belief that drugs are safe, especially over-the-counter products; and the plethora of healthcare providers, pharmacies, and Internet sites that supply drugs. These multiple options mean that an individual may receive drug prescriptions and recommendations from a variety of providers, many of whom may be unaware of the other prescribers’ actions. Direct-to-customer advertising exposes many more individuals to prescription drugs and proposed therapeutic indications of which they might have been previously unaware.[2,3] In addition to widespread public acceptance of drugs to treat illnesses, there is a growing appreciation of how agents may be used for prophylaxis against various diseases or for general health maintenance.

Even individuals who avoid taking specific drugs or agents may be exposed to pharmaceuticals through the food chain or in their daily environment.[4] The results of such exposure, including direct toxic reactions and reproductive toxicology, are beyond the scope of this chapter, although this area is likely to grow in importance over time.

This chapter presents a brief introduction and wide overview of the pharmacologic principles that form the foundation of pharmacotherapeutics in midwifery practice. These principles can be applied to specific pharmacotherapeutic therapies, which are addressed in other chapters. The examples included in this chapter are presented as illustrations to facilitate understanding of clinically relevant pharmacologic principles, effects, and properties; they are not a comprehensive summary of clinically relevant pharmacology for a particular topic. A list of resources is provided at the end of this chapter to assist the reader in obtaining a thorough

knowledge about when a specific drug is needed.

The terms “drugs,” “agents,” “medications,” and “pharmaceuticals” are used interchangeably throughout the chapter. The word “drug” does not connote an illicit substance or a licit substance being abused; rather, drugs with abuse potential are specifically designated as such. Drugs are listed by their generic names, followed by the most common brand name in parentheses.

The Lexicon of Pharmacology

As knowledge in pharmacology has expanded, so has the accompanying lexicon. A prerequisite to understanding drug actions and their effects is the midwife's ability to define the various terms used in pharmacology. A glossary presented in **Table 9-1**.

Table 9-1 Brief Glossary of Pharmacology

Term	Definition
Adverse drug reaction	Response to a drug that is noxious and unintended, and that occurs at doses normally used for prophylaxis, diagnosis, or therapy of disease or for the modification of physiologic function.
Agonist	A drug that binds to a receptor and activates it, producing a pharmacologic response.
Antagonist	A drug that attenuates the effects of an agonist. Antagonism can be competitive and reversible (i.e., the drug binds reversibly to a region of the receptor in common with the agonist) or competitive and irreversible (i.e., the antagonist binds covalently to the agonist binding site, and no amount of agonist can overcome the inhibition).
Behind-the-counter (BTC)	Descriptor for drugs that are sold without a prescription, but that are subject to restrictions such as proof of identity because of potential risks. For example, pseudoephedrine is BTC because it may be used as an ingredient in the production of methamphetamine.
Bioavailability	Percentage of an administered drug that is available to target tissues.
Bioequivalent	Pharmacologically equivalent.
Biovariability	Different expressions of a drug among individuals even when the agent is administered at a standard dose.
Black box warning	A notice from the U.S. Food and Drug Administration when unusual harm associated with an agent has been identified. A black box warning is added to package inserts after postmarketing studies identify unexpected risks linked to a drug.
Brand name	A trademarked name assigned to a drug by its manufacturer. Some brand names are similar to the generic name (e.g., pseudoephedrine/Sudafed); others suggest their indications for use (e.g., Tamiflu).
Chemical name	Although rarely used by prescribers and consumers, a name of a drug that describes its chemical composition.
Compounding	Mixing or combining ingredients to produce a pharmaceutical agent. Pharmacists may perform compounding to change the form from solid pill to liquid, or to create a unique dose and combination of products for a specific individual.
Controlled substance	One of the pharmaceuticals listed in schedules found in U.S. Law 21 U.S.C. §802(32)(A). These agents include opiates as well as non-opiates but generally have a high risk of addiction, and many lack a valid medicinal use. Examples include heroin.
Cosmeceutical	A cosmetic product that has medicinal benefits.
Counterfeit drugs	Pharmaceuticals that are produced and sold in a deceptive manner so that they appear to be authentic drugs.
Designer drug	A drug directed toward a specific biologic target that binds to and inhibits key molecules involved in a disease or pathologic event. Designer drugs often are older drugs whose composition is manipulated to minimize adverse effects. This term does not imply illicit drugs.
Direct-to-consumer (DTC)	Advertisements for selected drugs placed in popular media and directed to the general public, as opposed to being directed to providers.
Dispense (furnish)	The process of giving a drug to a consumer.

Drug	A chemical substance that brings about changes in a biologic system through its chemical action(s). Also called a *medication* or *pharmaceutical.*
Ecopharmacology	Derivation of drugs from plants, especially those found in the rainforest, as well as exploration of pharmacologic effects of pollutants in water that exert pharmaceutical-like effects, most often estrogenic in nature. The latter substances also have been called ecoestrogens or xenoestrogens.
Effectiveness	The ability of a drug or treatment to produce a positive effect in real-life circumstances or with typical use.
Efficacy	Ability of a drug or treatment to produce a positive effect in ideal circumstances such as a research trial.
Formulary	List of approved or available drugs. It is often used by insurers to identify agents that will be reimbursed or paid for by the insurer.
Generic name	A formulation that contains the same active ingredients found in the original brand formulation and is bioequivalent to that formulation.
Half-life	The period of time required for the concentration or amount of drug in the body to be reduced to exactly one-half of the initial concentration or amount.
High-alert drug	A pharmaceutical that is associated with significant harm if used in error.
Hypersensitivity reaction	A state of altered reactivity wherein the body reacts to a foreign substance with an exaggerated immune response; classified as Type I, II, III, or IV depending on the specific pathologic response.
Immunotherapy	Treatment of disease by inducing, enhancing, or suppressing an immune response.
Loading dose	A larger than normal dose administered as the first in a series of doses, with the other doses being equal to each other but smaller than the first. A loading dose is administered to achieve a therapeutic amount in the body more rapidly.
Nutraceutical (functional food)	A food or supplement that has specific health benefits.
Off-label use	Prescription or use of a drug for conditions other than those approved by the FDA.
Over-the-counter (OTC)	Pharmaceuticals sold without prescriptions.
Pharmacodynamics	How drugs produce their effects, such as interactions at a receptor site.
Pharmacogenetics	The study of how drugs interact with the genetic makeup of an individual or the genetic response to a drug; this may be one of the first clinical applications derived from the Human Genome Project.
Pharmacogenomics	Studies that illustrate similarities and differences in pharmacodynamic and pharmacokinetic mechanisms among various individuals and people of different ethnic backgrounds.
Pharmacokinetics	The movement of drugs in the body, specifically encompassing the study of factors that determine the amount of chemical agents at their sites of biologic effect at various times after the agent is administered. Pharmacokinetics encompasses four specific factors: absorption, distribution, metabolism (biotransformation), and excretion (clearance).
Pharmacotherapeutics	The field concentrating on the treatment effects of drugs. There are several subsections within pharmacotherapeutics.
Polypharmacy	The practice of treating individuals using multidrug regimens. This term generally is accepted to mean administration of five or more drugs.
Prescriptive authority	Legal ability to prescribe drugs, medical devices, or other regulated healthcare interventions.
Safety level	Plasma level or dose at which a drug's known adverse effects are not apparent.
Side effect	A physiologic response unrelated to the desired drug effects that occurs with therapeutic doses of the medication; it may be either beneficial or negative.
Therapeutic window	A point at which the plasma drug concentration is between the minimum effective

	concentration (MEC) in the plasma for obtaining the desired drug action and the mean toxic concentration (MTC).
Toxicology	The branch of pharmacology that deals with the nature, effects, and treatments of poisons.

Drug Categories and Naming Conventions

Drugs can be categorized in many different ways. For example, drugs can be described by the physiochemical property of the drug (e.g., an acid) or by the pharmacotherapeutic indication (e.g., sedative). Drugs also have chemical names, generic names, and brand names. The same drug could be identified by the chemical name ($C_{17}H_{21}NO$), the generic name (diphenhydramine), or the most common brand name (Benadryl).

Drug Development and Regulation

Drugs formulated as medications are approved for marketing by FDA. Pharmaceuticals for which the FDA has authority may be obtained by prescription, over the counter, or even behind the counter. The FDA also regulates medical devices such as intrauterine contraceptive systems (e.g., ParaGard, Mirena) and biologic agents such as vaccines. The FDA does not regulate dietary supplements, such as St. John's wort, although the agency does track adverse reactions that occur following use of dietary supplements. Similarly, the FDA may require labeling to designate that safety has not been established for cosmetics, although recall of cosmetics is voluntary by the manufacturer.

Drugs that are approved for specific use by the FDA must, in a series of preapproval studies that are submitted to the FDA for review, demonstrate both *safety* and *effectiveness* for a stated indication. Private-sector pharmaceutical companies conduct research, develop, manufacture, and market both prescription and *over-the-counter* (OTC) drugs. The FDA itself does not develop, manufacture, or test drugs. However, the Center for Drug Evaluation and Research (CDER), a subgroup within the FDA, oversees this process. Drug manufacturers submit full reports of clinical trials conducted on drugs, so that CDER can evaluate the data and determine whether the drug should be approved for a specific indication. This approval commonly is termed FDA labeling.

The preapproval clinical trials are intended to be appropriately large enough to determine safety and effectiveness. For a new drug to be introduced to the marketplace, several steps must occur. These steps are organized into four phases (**Figure 9-1**).[5] Phase 1 studies tend to be small and determine safety by exploring the basic pharmacology of the drug. Sometimes this phase is unnecessary because such studies have been conducted internationally and the information is already available. Phase 2 trials are designed to verify effectiveness. If the agent is intended to treat persons with a specific condition, the drug developer performs controlled clinical trials with members of that population. Phase 3 trials are randomized clinical trials with larger numbers of participants. Despite the larger size of the Phase 3 trials, many, if not most, adverse effects of drugs do not emerge until the postmarketing Phase 4. If risks or adverse reactions are identified after the drug is marketed, CDER takes action to inform the public, change a drug's label, or, when necessary, remove the product from the market.

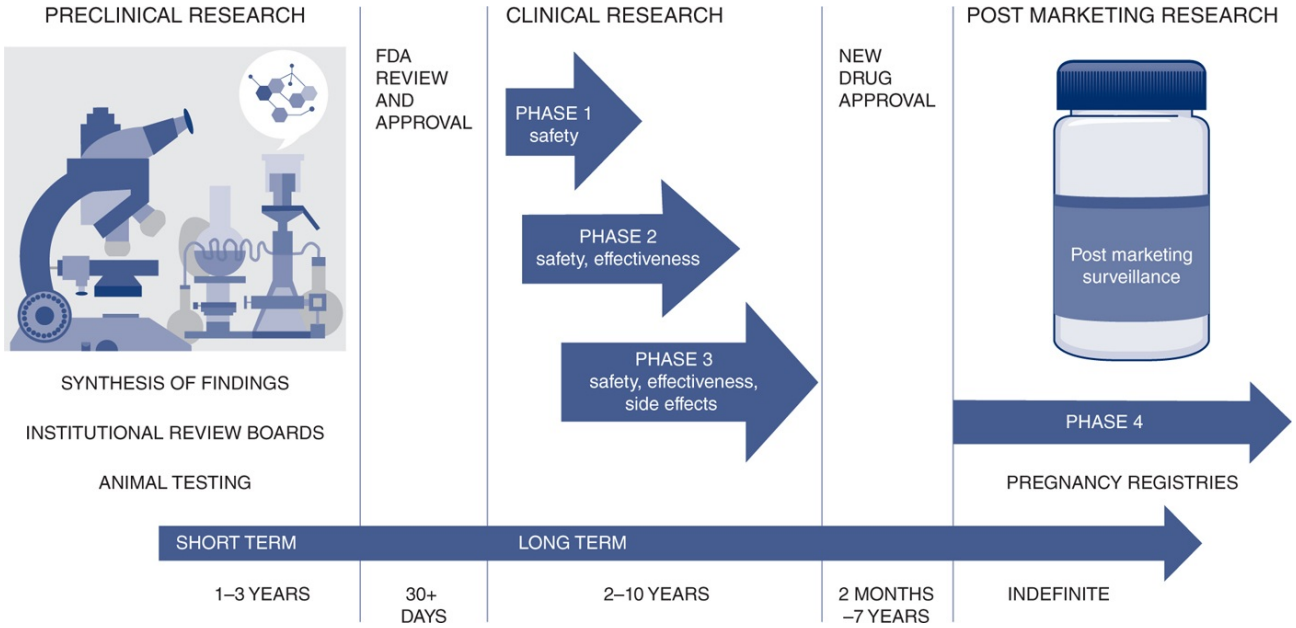

Figure 9-1 U.S. drug approval process.
Note: The lengths of time in the figure are approximate times.
Based on U.S. Food and Drug Administration. New drug approval process. Available at: https://www.drugs.com/fda-approval-process.html. Accessed August 17, 2017.[5]

Historically, children and women have not been participants in most drug development studies.[6] Although many reasons are cited to justify this exclusion, one factor is the changing environment in a woman's body over the course of the menstrual cycle, which could affect the pharmacokinetics and pharmacodynamics of a drug. Even when women do participate in clinical trials, analyses of gender differences in drug response are rarely published. Moreover, clinical trials for contraceptives generally do not include many adolescents, because women younger than 18 years are considered pediatric patients. Pediatrics itself is a difficult area in which to conduct clinical trials because of the inherent problems in obtaining informed consent and ethical concerns that drugs may adversely affect organs during growth and development.

After a drug receives FDA approval for treatment of a specific indication and becomes available for use, it may be prescribed for a different indication—a phenomenon called *off-label use*. Examples abound regarding off-label use.[7] For instance, the most commonly used tocolytic in the United States is magnesium sulfate, yet magnesium sulfate is not FDA approved for treating preterm labor. Methotrexate (Rheumatrex)—a folic acid antagonist used as a chemotherapeutic agent—has a marked predilection for destruction of trophoblastic tissue and is used off label for medical treatment of unruptured ectopic pregnancy. Although off-label use is common, it should not be undertaken capriciously. A legal liability potentially exists, especially if the drug is not widely used in practice for the off-label indication.

Controlled Substances

The U.S. Drug Enforcement Administration has a special role in the regulation of prescription drugs that have the potential for abuse, under the 1970 Controlled Substance Act (CSA). The CSA classifies pharmaceuticals that can be abused into one of five schedules based on the

substance's medicinal value, harmfulness, and potential for abuse or addiction. Schedule I is reserved for the most dangerous drugs that have no recognized medical use, such as heroin. Schedule V is the classification used for the least dangerous drugs, such as brand-name antitussives containing small amounts of codeine. Knowledge of these schedules is important for midwives with prescriptive authority, because prescriptive authority is often limited to specific schedules. **Table 9-2** lists the five schedules for controlled substances.

Table 9-2 U.S. Food and Drug Administration Classification of Controlled Substances

Schedule	Interpretation
I	High potential for abuse and no current accepted medical use. Examples are heroin and LSD.
II	High potential for abuse. Use may lead to severe physical or psychological dependence. Examples are opioids, amphetamines, short-acting barbiturates, and preparations containing codeine. Prescriptions must be written in ink or typewritten and signed by the practitioner. Verbal prescriptions must be confirmed in writing within 72 hours and may be given only in a genuine emergency. No renewals are permitted.
III	Some potential for abuse. Use may lead to low-to-moderate physical dependence or high psychological dependence. Examples are barbiturates and preparations containing small quantities of codeine. Prescriptions may be oral or written. Up to five renewals are permitted within 6 months.
IV	Low potential for abuse. Examples include chloral hydrate, phenobarbital, and benzodiazepines. Use may lead to limited physical or psychological dependence. Prescriptions may be oral or written. Up to five renewals are permitted within 6 months.
V	Subject to state and local regulations. Abuse potential is low; a prescription may not be required. Examples are antitussive and antidiarrheal medications containing limited quantities of opioids.

Modified with permission from U.S. Department of Justice, Drug and Enforcement Administration, Office of Diversion Control. Mid-level practitioners authorization by state. Available at: https://www.deadiversion.usdoj.gov/drugreg/practioners/. Accessed August 16, 2017.[8]

A registration number issued by the DEA is needed to prescribe a controlled substance. In 1993, the DEA published a regulation that established a new category under which healthcare providers other than physicians, dentists, veterinarians, or podiatrists could receive individual DEA registration numbers granting controlled substance prescribing privileges consistent with the authority granted them under state law.[8] Under this regulation, providers such as certified nurse-midwives and certified midwives were given authority to prescribe controlled substances if approved to do so by the state or jurisdiction in which they practice.

Regulation of Herbal Therapies

More than 2000 years ago, Hippocrates documented the use of more than 200 herbal remedies. Today, many herbs and botanicals are sold as dietary supplements, even though their actions and safety largely remain unknown. Under the Dietary Supplement Health and Education Act of 1994 (DSHEA), a manufacturer must ensure that its dietary supplement is safe before the product is marketed in the United States.[9] Effectiveness is not required for dietary supplements. The FDA is responsible for taking action against any unsafe dietary supplement

product after it reaches the market, but manufacturers are not required to register with the FDA or to seek FDA approval before producing or selling dietary supplements. The FDA's postmarketing responsibilities include monitoring safety concerns, through voluntary dietary supplement adverse event reporting. The FDA also monitors product information, such as labeling, claims, package inserts, and accompanying literature.

Much of the information available about the safety and effectiveness of herbs is anecdotal or reflects expert opinion. Some evidence-based information can be obtained, however. In 1978, a regulatory agency was established in Germany to evaluate the effectiveness of herbal remedies. Called the German Commission E, this group of 24 scientists evaluated studies (clinical, case, field) and prepared scientific monographs. By 2004, only herbs that the German Commission E found to be effective and to carry a low risk of adverse effects were expected to be available in Germany. Although the work of these scientists generally has been lauded, many common North American herbs are not included in the German registry.[10] An English translation of the German monographs has been published by the American Botanical Council.[11]

In the United States, the National Center for Complementary and Alternative Medicine (NCCAM) is currently conducting multiple studies that are comparing herbal remedies to conventional pharmaceutical treatments for specific conditions, such as endometriosis. Until such scientific evidence becomes available, claims involving therapeutic uses of herbs should be viewed with caution.

Prescriptive Authority

All 50 states grant some type of prescriptive authority to certified nurse-midwives.[1] Prescriptive authority remains less common for certified midwives, as their credential is newer and their numbers fewer. Prescriptive authority is controlled on the state level and ranges from very limited to relatively broad. Many states limit prescriptive authority according to the schedule of controlled substances. Some prescriptive authority laws are based on specific wording in state licensing laws or practice sites.

The Prescription

Midwives with prescriptive authority have the legal ability to write prescriptions. Although many prescriptions are phoned into a pharmacy or, increasingly, transmitted by electronic means, all prescriptions have some required components, most of which are established by state law and therefore vary from state to state. All handwritten prescriptions must be legibly written in indelible ink. Every prescription must include the midwife's name, address, and contact information. It is optimal to have the midwife's prescriptive authority number or other identifying information appear either on the top of the prescription order or adjacent to the midwife's signature. In some states, information about the midwife's collaborating physician must also be placed on the prescription. All prescriptions are dated, and information about the prescription is placed in the woman's record so that if she loses the prescription, changes pharmacies, or moves, it can be easily retrieved.

Only one drug can be written on each prescription blank. Refills, if any, are noted, as certain health plans limit coverage of drugs on a monthly basis. Permission to substitute a brand-name product for a generic drug is often included. Some authorities maintain lists of abbreviations that may be used on prescriptions, such as “tid” for “three times a day,” although use of any abbreviations is increasingly discouraged.

The section of the prescription specific to the medication consists of four parts: (1) superscription, (2) inscription, (3) subscription, and (4) signature. The superscription includes the symbol “Rx,” although according to World Health Organization guidelines, it is more proper to use the Latin “

”. In any case, this symbol is derived from the Latin word for “recipe” or “take.” The inscription specifies the ingredients and their quantities (e.g., nitrofurantoin 100 milligram capsules). In the inscription, it is important to avoid decimals and, where necessary, write words in full to avoid misunderstanding. For example, write “levothyroxine 50 micrograms,” not “0.050 milligram” or “50 mcg.” The subscription informs the pharmacist how to compound or dispense the medication (e.g., dispense 10 capsules). The signature, or “sig,” is not that of the prescriber, but rather represents the Latin “signa” or “mark” that provides the instructions that enable the woman to understand dosages and when to take a drug. The sig should include route, frequency, duration, and any other specific information—for example, “Take 1 capsule by mouth at bedtime for 10 days.”

In general, it is recommended that the generic or nonproprietary name be used when a prescription is written. Use of generic names enables the pharmacist to maintain a more limited stock of drugs and/or dispense the least expensive drug. However, if there is a particular reason to prescribe a brand-name drug, the trade name can be added. Some authorities allow generic substitution by the pharmacist and require the addition of “Do not substitute,” “Dispense as written,” or “Brand medically necessary” to the prescription if that brand, and no other, is to be dispensed. When a specific brand is required, the midwife should document that instruction in the woman’s chart, along with the rationale. This documentation is not only created for completeness, but also may be necessary for the prescription to be covered by a public insurance program such as Medicaid, various managed care groups, or other types of health insurance. **Figure 9-2** illustrates a sample prescription written appropriately by a midwife.

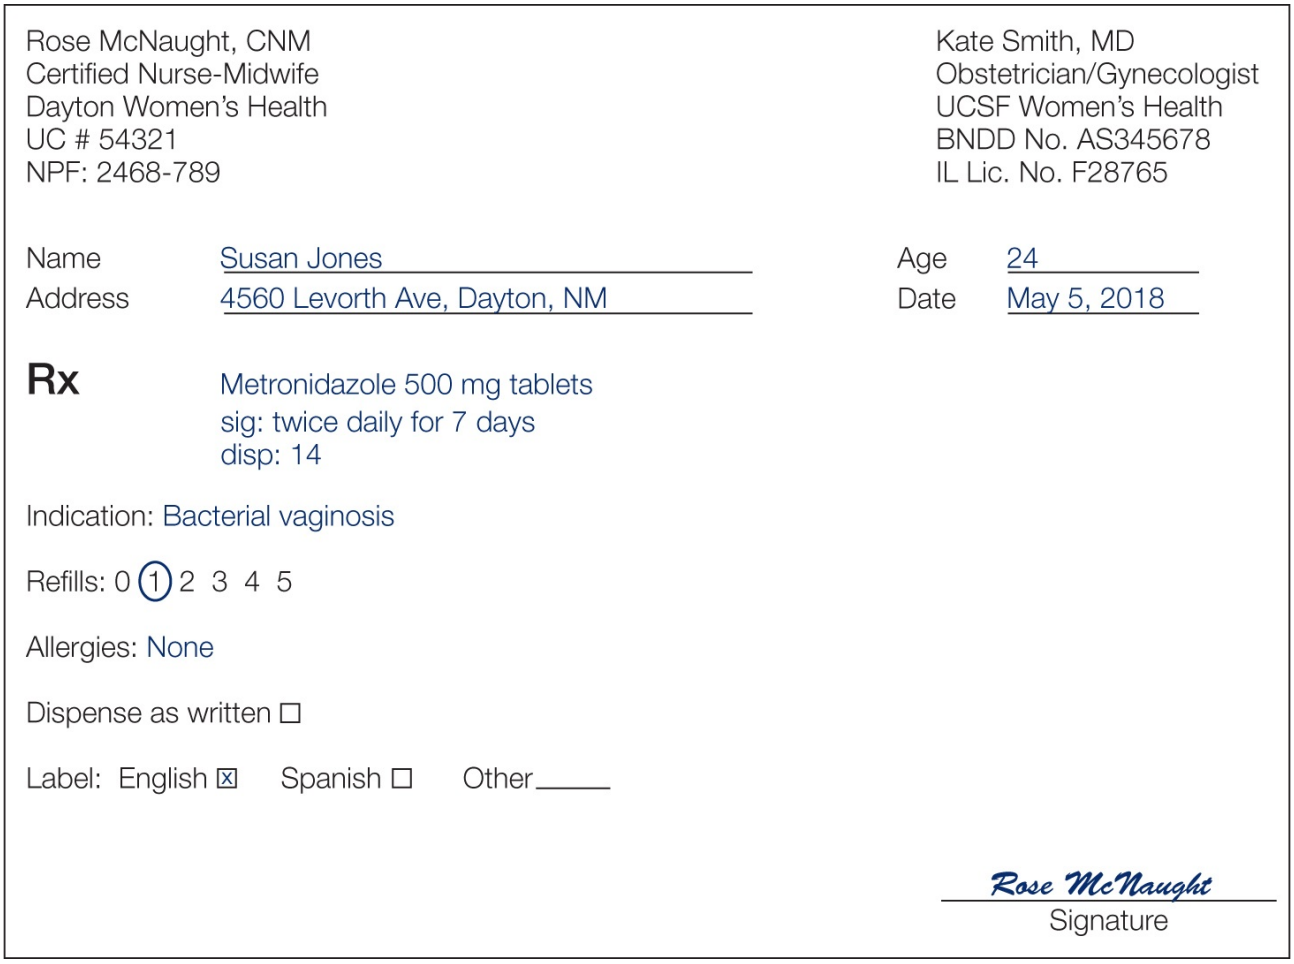

Figure 9-2 A sample prescription.

Principles of Clinical Pharmacology

Drugs undergo multiple biochemical transformations in the human body. Some are beneficial, some have no clinical effect, and some may be adverse effects. In addition, clinical situations such as pregnancy or renal disease can significantly alter an individual's response to a drug. To prescribe drugs safely, the clinician should be able to anticipate and recognize both the expected results and any adverse effects. A review of each drug's specific pharmacokinetics, pharmacodynamics, pharmacogenetics, and adverse effects supplies the knowledge that is needed to safely prescribe a drug in a manner that optimizes effectiveness.

Pharmacokinetics

Pharmacokinetics addresses the kinetics of drug absorption, distribution, metabolism, and excretion. Each of the four phases of pharmacokinetics effects how much of the drug reaches the target organ.

Absorption

Absorption is affected by the route of administration, pH of the drug, pH of the gastrointestinal tract, lipophilic or hydrophilic properties of the drug, entero-hepatic circulation (first-pass effect),[12] and the presence of other agents (drug–drug or drug–food interactions). The first-pass effect, which is also known as pre-systemic absorption, is most commonly associated with oral drugs. Pharmaceuticals administered orally must contain higher amounts of a drug to account for the loss that occurs through first-pass metabolism in the liver prior to the agent arriving in the circulation. When pharmaceuticals are administered using the transdermal route, such as hormone patches, the product may contain smaller amounts of the drug, as the active ingredient is directly absorbed into the circulation and avoids the initial metabolism by the liver.

Distribution

Distribution of the drug is affected by the size of the drug molecule as well as the drug's affinity for aqueous and lipid tissues, tissue permeability, systemic circulation, protein binding, and pH. There are two main phases of distribution: steady state and half-life. *Steady state* refers to the concentration of a drug in the systemic circulation when the rate of drug elimination equals the rate of drug availability. The *half-life* of a drug refers to the time it takes for the plasma concentration or the amount of drug in the body to be reduced by 50% (i.e., by half). Half-life determines the time required to reach steady state and, therefore, the time interval between doses. Steady state is usually reached after four to five half-lives, and elimination takes another four to five half-lives.

Another important pharmacokinetic concept when considering drug administration is *loading dose*. A loading dose is one or a series of doses that are given at the initiation of therapy so that the drug will reach the target plasma concentration rapidly. A loading dose is higher than the standard dose and is used to rapidly obtain a steady state when a quick therapeutic response is needed.

Protein binding can be one of the most important clinical factors in distribution of a drug. *Protein binding* refers to the fraction of total drug in the plasma that is bound to plasma proteins.[13] Albumin is the most common plasma protein that binds to drugs in plasma. Once bound to protein, the drug is altered or too large to diffuse out of the circulation and attach to a cell membrane receptor. Thus, only the unbound, or free, drug is distributed to its intended site of action in tissue. In turn, the drug's physiologic effect is related to the free drug concentration, rather than the total circulating plasma drug concentration.

Metabolism

Drug metabolism refers to the process by which a drug is chemically converted in the body so that it can be excreted via the kidney, feces, lung, or skin. The enzymes responsible for drug metabolism are mainly located in the liver, although some other tissues—such as kidney, lung, small intestine, and skin—also contain enzymes that metabolize drugs. The cytochrome P450 (CYP450) enzyme family is the group of enzymes that are responsible for the majority of drug metabolism reactions.[14]

For most drugs, metabolism results in changing the drug to a pharmacologically inactive compound; however, some drugs have no pharmacologic activity themselves, rather their metabolite is the active pharmacologic agents. These drugs are referred to as *prodrugs*. For example, valacyclovir (Valtrex) is not an effective antiviral drug, but its active metabolite, acyclovir, is active against herpes virus.[15]

Excretion or Clearance

Ultimately the amount of drugs removed from the body is the measurement of clearance. This calculation reflects the rate of drug excretion. Although most drugs are cleared through the renal system, some may be eliminated through other organs such as the lungs.

Pharmacodynamics

Pharmacodynamics refers to the relationship between the concentration of a drug in the systemic circulation and the biologic response that occurs, often termed the dose–response relationship. The minimum effective concentration is the lowest dose at which a desired response is noted.

Once at the target organ, a drug can act as an agonist, antagonist, partial agonist, or agonist–antagonist. *Agonists* elicit a pharmacologic response. Insulin and morphine are examples of drugs that act as receptor agonists. *Antagonists* do not activate the receptor when bound to it, so they prevent activation of the receptor by an agonist. Antihistamines are antagonists in that they block the histamine activated-receptor response to an allergen. A *partial agonist* elicits a partial pharmacologic response when bound to a specific receptor. *Agonist–antagonists* are similar to partial agonists but work via a different mechanism. These drugs affect receptors that have different forms, and they act as an agonist at one form and as an antagonist at another. For example, butorphanol (Stadol) blocks the effect of morphine at the mu opioid receptor but stimulates the kappa opioid receptor. The net result is analgesia that is not as potent as the

effect obtained with morphine.

Individual Variability in Drug Response: Pharmacogenetics, Race, and Gender

It has long been known that different individuals exhibit *biovariability*, or a different response to the same drug at a standard dose. Many drugs have wide variability in effectiveness for individuals.[16] This inter-individual variability in drug response may be due to extrinsic factors such as illness, smoking, diet, or drug–drug interactions; alternatively, it can be due to physiologic factors such as genetics, race, age, and gender.

Genetic differences account for approximately 15% to 30% of inter-individual differences in drug responses, and the field of pharmacogenetics is becoming more important clinically as knowledge about genetic influences on drug response proliferates. The two primary areas in which genetic differences affect drug response are metabolism by the CYP450 enzyme family and function of the cell receptors for drugs. Many variants, also known as polymorphisms, exist within the CYP450 enzyme family. CYP450 enzyme polymorphisms may result in a person being a poor (slow) metabolizer, an intermediate metabolizer, an extensive metabolizer, or an ultra-rapid metabolizer of a given medication.[17,18] When administered the same dose, persons who are poor metabolizers have elevated plasma concentrations of a drug and a greater risk of toxicity compared to persons who are extensive or ultra-metabolizers.[19] In contrast, a polymorphism that involves duplication of a specific CYP450 enzyme causes a person to be an ultra-rapid metabolizer of drugs that are metabolized by that enzyme, which can result in subtherapeutic responses to normal doses. Polymorphisms of the genes encoding the CYP enzyme family are distributed differently among racial and ethnic groups. For example, the prevalence of CYP2D6 ultra-rapid metabolizers is approximately 1% to 10% in Caucasians, 3% to 5% in African Americans, 16% to 28% in North Africans, and 21% in Asians.[18]

Differences in cell membrane receptors for drugs also lead to different pharmacodynamic responses. Polymorphic differences in drug receptors are differentially distributed among racial and ethnic groups. For example, persons of African American descent who have asthma are more likely to respond with exacerbations and increased morbidity when given long-acting beta-adrenergic agonists without concomitant therapy with an inhaled corticosteroid because the $beta_2$-adrenergic receptor downregulates (rather than upregulates) when those individuals are exposed to a $beta_2$-adrenergic agonist.[20]

The effect of gender is likely related to both drug metabolism and drug receptor differences. Sex hormones such as estrogen and progesterone modulate the activity of CYP450 enzymes. Thus, men and women may experience different drug effects despite adjustment of the dose for body size. In addition, estrogen may affect the function of drug receptors. A meta-analysis of gender differences in the response to opioids found morphine's effects are more potent among women than among men and the onset/offset of those effects is slower in women than in men.[21] Additional research is needed in this area before the evidence about gender differences in the response to pain medications can be applied clinically.

Clinical implications of pharmacogenetic differences are the current subject of research.

Genome-wide association studies have identified some populations who may benefit from genome testing to guide pharmacotherapy, and the FDA has added pharmacogenomic information to the drug label of such drugs.

Adverse Drug Reactions and Adverse Drug Events

Adverse drug reactions (ADRs) are unintended responses to a drug that occur when normal dosing is used. ADRs are quite common.[22,23] The term *adverse drug events* (ADEs) is a more inclusive category connoting any injury that results from the administration of a drug. ADEs includes adverse drug reactions, medication errors, overdoses, and known dose-related side effects.

After a drug has been determined to be safe and effective in preapproval clinical trials, it is prescribed for individuals in a broader population after approval—that is, for a more diverse group than the relatively select group who participated in the clinical trials. Thus, adverse effects of drugs are primarily identified during the postmarketing period. The Adverse Event Reporting Program of the FDA collects reports of ADRs via the FDA MedWatch program. Details of how to report an adverse drug reaction are listed in **Table 9-3**.

Table 9-3 How to Report an Adverse Drug Reaction

In 1993, the U.S. Food and Drug Administration (FDA) established *MedWatch*, a reporting system for adverse events or sentinel events. This system includes a computerized information database designed to support a postmarketing safety surveillance program for all FDA-approved drug and therapeutic biologic products.

Any suspected adverse events or reactions to medications, drug products, or medical devices (other than vaccines or investigational drugs) should be reported using FDA Form 3500 (available online at https://www.fda.gov/downloads/aboutfda/reportsmanualsforms/forms/ucm163919.pdf).

Information regarding the reporting of vaccine-related adverse event reports (VAERS) can be found at https://vaers.hhs.gov.

For individuals who prefer, the MedWatch program can be contacted by phone, fax, or mail, as well as online.

Phone: 1-800-332-1088

Fax: 1-800-FDA-0178

Mail: MedWatch
5600 Fishers Lane
Rockville, MD 20857

Adverse drug reactions are classified as either immune or non-immune reactions. Non-immune reactions are predictable. They include drug–drug interactions, drug overdose, and drug toxicity, and commonly occur secondary to known pharmacologic effects. Conversely, immune reactions, which are also called allergic reactions, are unpredictable. The four types of allergic or hypersensitivity reactions are listed in **Table 9-4**.

Table 9-4 Types of Hypersensitivity Reactions

Type	Timing of Reaction	Examples
Type I (immediate)	Minutes to hours after drug	Anaphylaxis from exposure to penicillin

	exposure	Hives following exposure to sulfa drugs
		Angioedema from ACE inhibitors
Type II (cytotoxic)	Variable	Transfusion reaction
		Hemolytic anemia from penicillin
Type III (immune complex formed)	1–3 weeks after drug exposure	Drug-induced lupus caused by minocycline (Minocin)
		Serum sickness caused by cefaclor (Ceclor)
Type IV (delayed or cell mediated)	2–7 days after drug exposure	Ampicillin rash
		Contact dermatitis caused by topical antihistamine

Abbreviation: ACE, angiotensin-converting enzyme.

Drug–Drug and Drug–Food Interactions

Adverse reactions may occur when certain drugs are used concomitantly, which is referred to as a drug–drug interaction. Adverse reactions may also occur when drugs are taken simultaneously with certain foods or botanical/herbal therapies. Assume drug A and drug B are both metabolized via the same cytochrome P450 enzyme. When these drugs are taken at the same time, drug A either inhibits or enhances the activity of the cytochrome P450 enzyme. In turn, metabolism of drug B is either inhibited, which results in higher plasma levels and perhaps overdose, or enhanced (i.e., it is metabolized more rapidly than usual), which results in a reduction of the plasma concentration of the drug, making it less effective. For example, the antifungal drug fluconazole (Diflucan) is an inhibitor of CYP2CP; when it is given to a person who is also taking tolbutamide (Micronase), the plasma concentration of tolbutamide increases and the individual becomes more likely to experience hypoglycemia. In another example, cardiac arrhythmias may occur when one of the macrolides erythromycin (E-base), azithromycin (Zithromax), or clarithromycin (Biaxin) is taken simultaneously with the antifungal ketoconazole (Nizoral).[24]

Pharmacotherapeutics in Primary Care

The drug categories most commonly used in primary care are vitamins, analgesics, antihistamines, antihypertensives, antimicrobials, hormonal formulations used for contraception, and immunizations. It is not possible to review these topics in depth in this chapter, and readers are referred to other texts for more detail. Instead, this section introduces pharmacologic considerations for analgesics, antimicrobials, and antihistamines—key drug categories that incorporate the pharmacologic principles and clinical implications that are inherent in all drug categories. References that have more in-depth information are provided where relevant.

Analgesics

Analgesic medications are categorized as non-opioid analgesics and opioid analgesics. Non-opioid analgesics include aspirin, acetaminophen (Tylenol), and nonsteroidal anti-inflammatory drugs (NSAIDs).[25] Opioid analgesics are a family of drugs with an action similar to morphine. For a variety of reasons, there is an epidemic of opioid overuse and overdoses in the United States; it is imperative for clinicians to appreciate and ensure the appropriate use of these agents.[26]

Analgesics have pharmacologic effects that are broad and affect many physiologic functions. Consequently, this category of drugs requires that the prescriber be especially aware of side effects and adverse effects. NSAIDs mitigate pain via their ability to inhibit cyclooxygenase (COX), the enzyme responsible for synthesizing prostaglandins.[27] Prostaglandins protect the gastric mucosa, inhibit platelet aggregation, and stimulate uterine contractions, in addition to mediating the inflammatory response and sensitizing pain receptors. Thus, these drugs can have multiple predictable side effects that can also be adverse effects.[28] Both gender differences and individual differences are noted in the pain response and in the response to many analgesics.[29-31] The various hormonal and genetic factors underlying these differences have yet to be fully elucidated.

Because analgesia may be potentiated when drugs that have different mechanisms of action are combined, it is common to combine an opiate with a non-opiate in one formulation. For example, the combination of acetaminophen and codeine comes in different strengths of acetaminophen (e.g., Tylenol #1, #2, or #3). Combination drugs have additional pharmacologic implications. For example, although the acetaminophen/codeine combinations are usually prescribed on the basis of the 30 mg of codeine in each tablet, the maximum dose is actually limited by the maximum dose of acetaminophen that is safe to take in a 24-hour period (i.e., 4 grams/24 hours). When choosing a specific formulation, the analgesic capability of a particular formulation should be assessed and matched to the pain control needs of the woman.[30]

Increasing concerns about treating pain have resulted in a marked increase in the use of and prescriptions for opioids over the last decade. Unfortunately, this trend has resulted in a significant rise in the prevalence of opioid misuse.[32,33] Strategies for treating pain without increasing the risk of opioid misuse are currently the subject of much research. In addition, several states have implemented policies or regulations that guide opioid prescribing.[32-35]

Data are constantly emerging on this topic.

Antimicrobials

Antimicrobial drugs include agents directed against bacteria, fungi, viruses, and parasites. Each type of microorganism targeted by these drugs has a different biochemical structure, and consequently each type of antimicrobial has a different chemical structure and biochemical action. In general, antifungal and antiviral drugs attack protein structures that are not present in human cells, so these drugs are less likely to have adverse side effects. At the other end of the spectrum are drugs directed at parasites, which are multicellular organisms that share many similarities with human cells. Safe and effective antiparasitic drugs are particularly difficult to create.

Antimicrobials and analgesics are the most common prescriptions written in primary care practice. Unfortunately, drug resistance is an increasingly problematic trend that is directly related to the overuse of antibiotics for conditions that do not actually require an antimicrobial agent.[36-39] Thus, the first step when using these agents is to make sure they are required. Eight principles describe the critical clinical considerations that must be taken into account prior to prescribing an antimicrobial drug:

1. Confirmation of the presence of an infection through history and physical examination
2. Identification of the pathogen when possible
3. Confirmation of the need for an antimicrobial agent rather than use of palliative therapies and infection control measures
4. Understanding of host factors that may influence pharmacodynamics as well as the individual's concerns and resources
5. Selection of an appropriate antimicrobial agent using the dual principles of narrowest spectrum and shortest effective duration possible
6. Knowledge of the pharmacokinetics and pharmacodynamics of selected medications
7. Education of the individual and family regarding appropriate use of the antimicrobial
8. Appropriate monitoring of the therapeutic response[38]

Antibacterial drugs are either bacteriostatic (i.e., they inhibit bacterial growth) or bacteriocidal (i.e., they kill bacteria) in nature. More generally, these agents are classified by their mechanism of action: (1) They attack the cell wall (penicillins, cephalosporins, and vancomycin); (2) they inhibit or alter protein synthesis (macrolides, tetracycline, and aminoglycosides); or (3) they interfere with bacterial DNA (fluoroquinolones, antiprotozoan drugs, and isoniazid [INH]).

Inappropriate prescribing of antibiotics for viral infections and use of third- and fourth-generation broad-spectrum agents when a narrow-spectrum agent is available are by far the most important problems facing midwives who may be prescribing these agents. There are two critical components to the solution to these problems. First, clinical guidelines are available from most professional associations as well as individual institutions; these guidelines can help the prescriber choose the correct therapy. Second, thorough health education that is both

culturally sensitive and provided at the correct health literacy level is essential. As a corollary to this general rule, when an antimicrobial agent is prescribed, detailed information about dose, timing, specific rules about taking the medication with food or drink, and possible side effects or adverse effects is also part of the required health education.

Drug Resistance to Antimicrobials and Antibiotic Stewardship

Shortly after drug manufacturers began mass production of penicillin in the 1940s, infections secondary to resistant *Staphylococcus aureus* began to appear. The subsequent spread of antibiotic resistance occurred rapidly.[40] This rise in antibiotic resistance has been directly correlated with increased use of antimicrobials.[41]

Several factors account for the development and rapid rise of drug-resistant strains of bacteria. One factor is the human complacency that developed in the 1980s, when many scientists and clinicians began to view bacterial infections as easily curable conditions. Antimicrobial agents were used liberally, even for conditions for which they were not indicated, such as the common cold. When susceptible bacteria were eradicated, the few survivors were those organisms that were resistant to the antimicrobial agent. Through natural selection, these microbes then became the predominant microorganism. Interestingly, use of antibacterial soaps and cleansers may contribute to this problem. The antibacterial agents added to a variety of substances, such as soaps, lotions, and cleaning supplies, can act like antibiotics in the selection of resistant strains of microbes; these products are no more effective than similar agents without the antibacterial additives, and controversy has arisen regarding whether they may contribute to drug resistance.[36]

Resistant microbes have several mechanisms of action. For example, penicillin resistance is the result of gene action. Because penicillin inhibits enzymes involved in cell wall synthesis, some organisms may alter their cell walls so that the antibiotic cannot bind to it. These organisms are called beta-lactamase inhibitors because they produce an enzyme called beta-lactamase that breaks open the beta-lactam ring of the penicillin molecule.[42] In contrast, resistance to quinolones emerges when organisms evolve in a way that alters the ability of the drug to penetrate its target.[43]

Bacteria can acquire genes that provide resistance to antimicrobial drugs in one of three ways: (1) spontaneous DNA mutation (e.g., drug-resistant tuberculosis); (2) transformation in which one bacterium acquires and then replicates DNA from another bacterium (e.g., penicillin-resistant gonorrhea); and (3) resistance acquired from a small circle of DNA called a plasmid that can move from one type of bacterium to another (e.g., *Shigella*). The third type is the most troublesome, because following plasmid acquisition, the bacteria may simultaneously become resistant to several types of drugs.

Antibiotic stewardship refers to a coordinated program that addresses “the optimal selection, dosage, and duration of antimicrobial treatment that results in the best clinical outcome for the treatment or prevention of infection, with minimal toxicity to the patient and minimal impact on subsequent resistance.”[39,44,45] Antibiotic stewardship programs focus on use of appropriate antimicrobials, decreasing overuse and misuse of these agents, and minimizing the development of antibiotic resistance. Many hospital settings now have antibiotic

stewardship teams. Examples of antibiotic stewardship interventions include limitations on formularies, computer-aided decision support programs, and feedback to clinicians about their prescribing practices. These techniques have been shown to be both effective and cost saving.[37-39] A useful mnemonic when writing a prescription for an antibiotic is to consider the following four items: Right Drug, Right Dose, De-escalation to pathogen-directed therapy, and Right Duration of therapy.[46] The Resources section at the end of this chapter includes resources related to antibiotic stewardship.

Antihistamines

Four different types of histamine receptors (H_1, H_2, H_3, H_4) are found in multiple tissue sites within the body. Antihistamine drugs that target these receptors have a wide range of actions and uses. Antihistamines are common OTC medications.

H_1 receptors are found in the muscles that line blood vessels (vascular smooth muscle) and in nervous tissue. These receptors are involved in the inflammatory response and allergic reactions. H_2 receptors are located in the gastric mucosa. Stimulation of these receptors causes secretion of gastric acid. H_3 and H_4 receptors are found in the brain, heart, eye, and breast tissues, as well as in immune cells. These receptors appear to be involved in circadian rhythms, allergic reactions, and perhaps carcinomas, although their exact functions are not yet well elucidated.

Antihistamines that act as antagonists at H_1 receptors are used to treat allergic reactions, nausea and vomiting, and motion sickness. First-generation H_1 antihistamines have a duration of action of approximately 4–6 hours and can affect different types of histamine receptors. These drugs cross the blood–brain barrier and cause sedation—the most common side effect associated with antihistamines. When sedation is the desired effect, it is important to note that tolerance to sedation develops within a few days. Thus, drugs such as diphenhydramine hydrochloride (Benadryl) and doxylamine succinate (Unisom Sleep Tabs) should be taken for a few days only.

The other side effect of antihistamines that is of clinical concern relates to their anticholinergic effects. This action causes a drying of mucous membranes, which is helpful in treating allergies, but can cause urinary retention and blurred vision. The primary contraindications to antihistamines are those wherein sedation or anticholinergic effects would cause adverse outcomes. For example, persons with glaucoma or hyperthyroidism should not use antihistamines.

The second-generation H_1 antihistamines have a longer duration of action, which can be as long as 24 hours. In addition, they are more selective for peripheral H_1 receptors and, therefore, do not cause sedation. The second-generation H_1 antihistamines, however, have more drug–drug interactions than do the first-generation drugs in this category.[47]

The H_2 antihistamines are used to treat gastric disorders in which hyperacidity is a problem. These antihistamines have very few side effects. Cimetidine (Tagamet) has many drug–drug interactions and, for this reason, is not considered the first H_2 antihistamine of choice.

Famotidine (Pepcid AC) is more potent than either cimetidine (Tagamet) or ranitidine (Zantac). The most common side effect of these drugs is headache, which occurs in 3% to 5% of persons who take these medications.

Use of Drugs During Pregnancy

Two key considerations must be taken into account when prescribing a drug for pregnant women: (1) physiologic changes of pregnancy that affect drug dosage and (2) effects of the drug on the fetus.

Pharmacokinetics in Pregnancy

The myriad physiologic changes that occur during pregnancy affect the pharmacokinetics of any drugs and herbs that the pregnant woman uses.[48] Pregnancy-related changes in pharmacokinetics, and some clinical examples of those changes, are summarized in **Table 9-5**.[48,49]

Table 9-5 **Pregnancy-Related Changes in Pharmacokinetics**

Pharmacokinetic Phase	Pregnancy Changes	Clinical Implications
Absorption	Increased progesterone production causes decreased intestinal motility and a 30–50% increase in gastric emptying time	Gestational nausea and vomiting may impair absorption
		Slower gastric emptying time may delay the onset of the drug response
	Gastric pH increases at midgestation	Increased exposure to bacteria in the intestine may decrease the bioavailability of some drugs
		Calcium and iron bind when ingested concurrently, thereby decreasing absorption of both minerals
Lung absorption	Respiratory minute volume increases approximately 50%	Dose requirements for inhaled drugs are decreased
Transdermal, subcutaneous absorption	Skin perfusion and skin hydration are both increased	Both lipophilic drugs and hydrophilic drugs are more rapidly absorbed transcutaneously
	Enhanced perfusion to muscles	Intramuscular absorption of drugs is more rapid and complete compared to absorption in nonpregnant individuals
Distribution	Plasma volume is expanded by approximately 50%	Hydrophilic drugs have reduced plasma concentration and need to be given in higher doses
	Body fat stores increase by 3–4 kg	Lipophilic drugs that concentrate in body fat may accumulate, such that prolonged effects could be seen following long-term use
Protein binding	Plasma albumin concentrations are reduced secondary to increased plasma volume	Increased free drug is available to exert pharmacologic effects
		Drugs that are highly protein bound will have more pharmacologic activity in a pregnant woman
Fetal–maternal distribution	The fetal compartment is available for distribution of drugs	The concentrations of most drugs in the fetal compartment tend to be 50–100% of the concentration in the maternal compartment
	The fetal circulation is more acidic than the maternal circulation	Highly lipophilic drugs of low molecular weight that have low protein binding can accumulate in the fetal compartment
	Fetal albumin concentration in plasma increases throughout pregnancy and is 20% higher than the maternal	Basic drugs such as meperidine (Demerol) can

	concentration at term	have higher concentrations in the fetal compartment than in the maternal circulation secondary to “ion trapping” Drugs that are highly bound to albumin can concentrate in the fetus at term
Metabolism	Changes in estrogen and progesterone affect cytochrome P450 enzyme activity CYP1A2 is inhibited CYP3A4 and CYP2C9 are increased	Metabolism of caffeine and theophylline (Theo-Dur) are inhibited or slower Metabolism of sertraline (Zoloft) and metoprolol (Lopressor) is enhanced or faster
Elimination	Glomerular filtration rate increases by 50% throughout pregnancy	More rapid clearance of most drugs that are eliminated renally

Some medications need dosage adjustments for pregnant women. For example, aminoglycosides such as gentamicin (Garamycin), as well as other antibiotics such as ampicillin (Omnipen, Polycillin, Principen) and cefazolin (Rocephin), achieve lower serum concentrations during pregnancy; therefore, to be effective, the doses of these medications need to be increased for pregnant women. Ampicillin, in particular, has serum concentrations in pregnant women that are 50% of the serum concentrations seen in nonpregnant women.[50,51]

Transport of Drugs Across the Placenta

Drug distribution is complex during pregnancy, as four separate compartments exist: (1) the fetus, (2) the amniotic fluid, (3) the placenta, and (4) the mother. Each of the compartments affects movement of drugs, and occasionally one compartment will have a higher concentration of drug than another.[52,53]

For a drug to move from the maternal circulation to the fetal circulation, it must transfer across the physical barrier between maternal and fetal circulation. The methods available for this transfer are diffusion, active transport, and movement via protein transporters. Most drugs move across the placental membranes by simple diffusion, although some take advantage of carrier-mediated mechanisms or use facilitated diffusion. Neither of these two methods requires energy or allows an agent to be transferred across the membrane to an area of higher drug concentration. Glucocorticoids and cephalexin (Keflex), for example, are transported via facilitated diffusion. This mechanism is utilized for transport of endogenous compounds such as hormones; likewise, it is used to transport drugs that are structurally similar to naturally occurring hormones.

Unlike passive transport, active transport requires energy. Pinocytosis is the most commonly used active transport method, a process during which a portion of the plasma membrane engulfs the drug molecule, creating a type of intracellular vesicle. Because of the energy and time required for pinocytosis, the small number of drugs that cross the placenta using active transport are also similar in structure to endogenous compounds that cross the placenta this way. Digoxin (Lanoxin) and valproic acid (Depakene), for example, cross the placenta via active transport.

The functions of protein transporters are quite interesting. These proteins extend from the intracellular space across the cell membrane into the extracellular space. Their function is to move substances from the placenta back into the maternal circulation. The protein transporters

(e.g., P-glycoprotein and multidrug resistance proteins 1, 2, and 3) protect the fetus from some drugs via this efflux mechanism.[13]

Drug transfer across the placenta is affected by various characteristics of the drug, including its size (molecular weight), lipid solubility, plasma protein binding, and acid versus basic properties.[48-54] Most drugs have a small molecular weight, usually less than 500 daltons (Da), so they are easily transferred across the placenta. Drugs with a molecular weight greater than 500 Da transfer incompletely; those that have a molecular weight greater than 1000 Da, such as heparin and insulin, transfer very poorly. Drugs that are more lipophilic cross the placenta more readily than those that are hydrophilic, as the placenta is lipoid in character. A non-ionized state facilitates transfer. When ionized basic drugs such as meperidine (Demerol) cross the placenta, they can accumulate in the fetal liver and adrenal glands and become ion-trapped in the fetus because the fetal circulation is more acidic than the maternal circulation.

Once a drug enters the fetal circulation, it is free to bind with proteins in the fetal plasma. Notably, albumin concentrations in the fetal compartment are higher than those in the maternal compartment. As a consequence, some highly protein-bound drugs such as diazepam (Valium) may have an increased fetal effect when compared with their maternal effects.

Teratogenic and Fetotoxic Effects of Drugs

Although most women do not plan to take drugs during pregnancy, almost 50% of all pregnancies are unintended and awareness of pregnancy typically occurs only after embryogenesis has begun. Thus, pregnant women may unknowingly be prescribed teratogenic medications.[55,56]

Teratology is essentially the study of congenital anomalies and teratogens or any agent that irreversibly alters growth, structure, or function in a developing embryo or fetus. Teratogens include viruses such as rubella, chemicals such as mercury, and drugs such as diethylstilbestrol (DES).[52,55-60] The term *fetotoxic* is used to describe agents, such as tobacco, that have toxic effects on the fetus and adversely affect growth or development.[57] The fetus is mostly likely to be exposed to teratogenic agents in the first trimester and to fetotoxic agents in the second and third trimesters.

Overall, birth defects occur in approximately 1% to 3% of all births.[58] This percentage is often called the “background risk” upon which additional risks are calculated based on family history, past history, and environmental exposure. Only 10% of birth defects can be associated with environmental factors, and the majority of environmental factors are not pharmaceutical. Drugs and chemical agents such as mercury and pesticides account for approximately 45% of the environmental teratogens involved in congenital anomalies. Drugs alone account for only 2% to 3% of all birth defects.[57-60]

The unique fact about teratogenic medications is that avoiding the teratogen can prevent the associated congenital anomaly. For this reason, knowledge of teratogenic drugs is essential for the practicing midwife. Fortunately, the number of teratogenic agents is relatively small, and even fewer are in common use.

The preimplantation period is considered the “all or nothing” period. If a small number of cells are damaged during this time period, the fetus usually compensates without any damage.

Conversely, if a large number of cells are damaged, the embryo will be lost and a spontaneous abortion will occur. The period of organogenesis—between 2 and 8 weeks post fertilization, or 4 to 10 gestational weeks—is the most critical period wherein teratogenic exposures can cause fetal malformations (**Figure 9-3**).[61] **Table 9-6** lists drugs that are known to have teratogenic or fetotoxic effects.

Table 9-6 Drugs That Have a Teratogenic or Fetotoxic Effect

Drug Category Name (Brand Name)	Teratogenic or Fetotoxic Effects	Clinical Implications
Androgens and testosterone derivatives: Danocrine (Danazol)	Virilization of females Advanced genital development of males	Dose dependent and based on critical period. Brief exposure rarely is significant. Before 9 weeks' gestation, labioscrotal fusion is common. Incidental, brief exposure usually has minimal risk.
Antibiotics: **Tetracyclines:** Tetracycline (Terramycin) Doxycycline (Adoxa)	Abnormalities of teeth discoloration	Critical period is after first trimester. Discoloration of permanent teeth is possible if exposure occurs after 24 weeks' gestation. No well-controlled studies of doxycycline have been performed, but case-controlled studies suggest it is not associated with teratogenic risk. Recommend that doxycycline be used only if it is the only effective agent.

Sulfonamides: Sulfamethoxazole (Bactrim, Septra)	Hyperbilirubinemia in neonates	Contraindicated in third trimester.
Chloramphenicol	Grey syndrome in neonates 2–9 days after therapy is administered	Oral chloramphenicol is contraindicated in pregnancy.
Aminoglycosides: Gentamycin Streptomycin Kanamycin	Neonatal ototoxicity	Streptomycin and kanamycin when administered in high doses to treat tuberculosis, has a clear risk of fetal ototoxicity. The risk associated with gentamycin may be smaller, but these antibiotics are not recommended for use in pregnancy.
Anticonvulsants: Carbamazepine (Tegretol) Phenytoin (Dilantin) Trimethadione (Tridione) Valproic acid (Depakene) Valproate (Depacon)	1% risk of neural tube defects, cardiovascular defects, developmental delays, and intrauterine growth restriction Reduced intelligence associated with use of valproic acid or valproate Phenytoin is specifically associated with cardiac defects and cleft palate	Critical period is all trimesters. Risk of neural tube defects is increased with use of anticonvulsants, especially when they are used with other antiepileptic drugs. Risk of neural tube defects is decreased with increased folic acid supplementation. Polytherapy with more than one anticonvulsant increases risk. Newer anticonvulsants such as gabapentin (Neurontin) do not appear to engender a risk of congenital anomaly.
ACE inhibitors: Captopril (Capoten) Enalapril (Vasotec) Lisinopril (Prinivil)	Intrauterine growth restriction Oligohydramnios Renal failure Decreased skull ossification Renal tubular dysgenesis	Risk of growth restriction is approximately 25%, with fetal morbidity of approximately 30%. Risk of adverse effects increases in the second and third trimesters (probably due to decreased uteroplacental flow). Beta blockers such as labetalol (Trandate) are safe in pregnancy.
Antidepressants: Fluoxetine (Prozac) Paroxetine (Paxil) Sertraline (Zoloft)	Paroxetine increases the risk of cardiac defects 1.5- to 2-fold; the other selective serotonin reuptake inhibitor–type antidepressants do not appear to have teratogenic effects Exposure in the third trimester is associated with neonatal withdrawal Persistent pulmonary hypertension noted in case reports	Overall, risks of teratogenic and fetotoxic effects are low. Antidepressants should not be discontinued during pregnancy. If starting antidepressant therapy during pregnancy, avoid the use of paroxetine.
Antineoplastic drugs: Cyclophosphamide (Cytoxan) Methotrexate (Rheumatrex)	Multiple birth defects and spontaneous abortion if used in the first trimester	If a woman needs one of these drugs, refer her for consultation with perinatologists and oncologists. Methotrexate is used to treat ectopic pregnancy.
Angiotensin II receptor blockers: Losartan (Cozaar)	Prolonged renal failure and hypotension in the newborn, decreased skull ossification, and renal tubular agenesis	Critical period is all trimesters.
Antithyroid drugs: Propylthiouracil (PTU) Methimazole (Tapazole)	Fetal and neonatal goiter, fetal hypothyroidism, and aplasia cutis are associated with methimazole but not propylthiouracil	Critical period is all trimesters. Women who need to take antithyroid drugs will generally be counseled to take propylthiouracil. The risk of fetal goiter is approximately 1–5%.

Aspirin	More than 150 mg/day is associated with prolonged gestation, prolonged labor, bleeding complications in the neonate, premature closure of the ductus arteriosus, and intrauterine growth restriction	Critical period is all trimesters. Although low-dose aspirin may be of benefit for women with antiphospholipid syndrome or lupus, normal adult doses should be avoided.
Benzodiazepines: Alprazolam (Xanax) Chlordiazepoxide (Librium) Diazepam (Valium)	Increased risk of neonatal withdrawal Some studies show increased risk of oral clefts with first-trimester exposure to diazepam	Early data on the association between benzodiazepines and oral cleft are controversial. Benzodiazepines are highly lipophilic and have a long half-life in the neonate.
Corticosteroids: Methyl prednisone (Medrol)	Possibly increased risk of oral and cleft defects	Critical period is first trimester. Because the risk is low, oral corticosteroids are used in the first trimester to treat hyperemesis gravidarum and other medical conditions. No risk associated with topical use.
Coumarin (Warfarin)	Bone defects Growth restriction CNS defects Developmental delays	15–25% risk when anticoagulants that impair vitamin K are used, especially between 6 and 9 weeks of gestation. Later use in pregnancy is associated with abruption, CNS defects, stillbirth, and hemorrhage of the fetus/newborn.
Ergot alkaloids: Ergotamine (Cafergot)	Spontaneous abortion Mobius syndrome Intestinal atresia Cerebral developmental abnormalities Low birth weight and preterm birth	Critical period is all trimesters. Sumatriptan (Imitrex) is an alternative to ergotamine for acute migraine treatment.
Folic acid antagonists: Methotrexate (Rheumatrex) Carbamazepine (Tegretol) Phenytoin (Dilantin) Phenobarbital (Solfoton) Primidone (Mysoline) Trimethoprim (Trimpex)	Spontaneous abortion Neural tube defects Cardiovascular defects Urinary tract defects	Drugs in many different drug categories are folic acid antagonists. Some sources suggest that the risks can be decreased with folic acid supplementation. Trimethoprim is a component of trimethoprim–sulfamethoxazole (Septra), which is commonly used to treat urinary tract infections. This drug should not be given in the first and third trimesters.
Lithium (Lithobid)	Cardiac defects Epstein's anomaly	Absolute risk is small, but alternative drugs should be recommended if possible.
Mifepristone (RU-486)	Antiprogestogen; used as an abortifacient Human data are limited	Primarily used for abortion in combination with misoprostol. Less effective when used alone.
Misoprostol (Cytotec)	Abortion Moebius sequence (brain stem ischemia, vascular disruption) for misoprostol	Potent uterostimulant capable of initiating uterine contractions at all gestational ages.
Nonsteroidal anti-inflammatory drugs:	Theorized premature closure of the ductus arteriosus Necrotizing enterocolitis	Contraindicated in general but especially in the third trimester.

Ibuprofen (Advil) Naproxen (Aleve)		
Retinoids: Isotretinoin (Accutane)	Multiple birth defects, including CNS, cardiac, and endocrine damage	Oral isotretinoin is contraindicated in pregnancy. Topical preparations are unlikely to have serious teratogenic effects but are still contraindicated because other agents can be used.
Statins: Atorvastatin (Lipitor) Lovastatin (Mevacor)	Interfere with cholesterol production Primarily have theoretical adverse effects on the fetus	Contraindicated in pregnancy.
Other: Thalidomide	Limb deficiencies Cardiac and gastrointestinal abnormalities	20–30% risk during critical period (very potent). Used for years before its teratogenic effects became obvious. Has caused the belief that all drugs have the potential to be a "new thalidomide." Back on market for treatment of oral lesions in HIV infection, Hansen's disease, tuberculosis, and multiple myeloma. STEPS is available online from the manufacturer, Celgene.

Abbreviations: ACE, angiotensin-converting enzyme; CNS, central nervous system; HIV, human immunodeficiency virus; STEPS, System for Thalidomide Education and Prescribing Safety.

U.S. Food and Drug Administration Pregnancy and Lactation Labeling System

In 1979, the FDA published a set of pregnancy risk categories for prescription and nonprescription drugs, including those with known teratogenic effects.[62] The letter-based categories A, B, C, D, and X were designed to indicate drug safety for the fetus. Although the FDA created the drug categories, the drug manufacturer determines the category to which a particular drug will be assigned.[6] Unfortunately, these FDA pregnancy categories oversimplified the complexity of what is known and what is not known about drug effects on human fetuses, in several different ways.[63]

In 2015, the FDA replaced the five letter categories with a more comprehensive narrative labeling system, the FDA Pregnancy/Lactation Labeling Rule (PLLR). The new labeling requirements address the safety of drugs in three settings: (1) pregnancy and intrapartum, (2) lactation, and (3) use of drugs by women and men with reproductive capability (**Table 9-7**).[62-64] Each section contains subsections that address risk information, clinical considerations, and background data.[62,64] In these sections, information from animal studies and human studies are listed separately.

Table 9-7 **Summary of the 2015 U.S. Food and Drug Administration Pregnancy/Lactation Labeling Rule**

General Information	Fetal Risk Summary	Clinical Considerations	Background Data
8.1 Pregnancy			
Inclusion of statement on background risk Contact information about scientifically, FDA acceptable pregnancy registries	Information from all relevant sources Risk conclusion regarding developmental abnormalities in humans and other relevant risks: whether it is likely that the drug increases the risk If increased risk is identified by human data, a narrative will be included If data demonstrate the drug is not systemically absorbed, a statement is included that maternal use is not expected to result in fetal exposure When the drug is systematically absorbed, statements of risk are divided based on type of data: human or animal, with findings from human studies presented first[a]	Statement on inadvertent exposure in early pregnancy: whether there is information or not Description of any known risks to the woman and fetus from the untreated disease Dosing adjustments during pregnancy Maternal adverse effects of the drug that are unique or increased during pregnancy Effects of dose, timing, and duration of treatment with the drug during pregnancy Potential neonatal complications and interventions needed If the drug may potentially be used on an intrapartum basis, even if not for an FDA-approved indication, information will be included about the effects on woman and the fetus/newborn, duration of labor and birth, risk of complications including the need for interventions, and long-term potential effects on the child	Include study type, dose, duration, timing, and results, including fetal abnormalities or other adverse effects Human data are presented first, including positive and negative effects, number of subjects, and study duration Animal study data include the species involved and recalculation of doses into human dose equivalents

8.2 Lactation			
General information is not mandated in the rule	Information from all relevant sources is included and identified Statement that the drug is compatible with breastfeeding if it does not have any effect on the quality or quantity of milk, if it is nondetectable in milk, or if no adverse effects are found in the child As applicable, a summary of the drug and its effects on milk production, its presence in milk, and any effects on the child[b]	Label will provide the following information, when available: • Strategies to minimize exposure to the child, including application of topical drugs to the nipple • Information about potential drug effects that could be useful to caregivers, such as monitoring for adverse effects, how to respond when they occur, and information about adjustments of maternal doses	Overview of the data that are the basis of the risk summary and clinical considerations Human data to be presented first
	Risks	**Clinical Considerations**	
8.3 Females and Males of Reproductive Potential			
	Risks are not specially noted as part of the information for females and males of reproductive potential, but the following address when it must be included and imply risks: • When pregnancy testing and/or contraception are required or recommended before, during, or after drug therapy • When there are human and/or animal data that suggest drug-associated fertility effects	Clinical considerations are not specifically noted as part of the information for females and males of reproductive potential, but the following list content of potential clinical importance must be included, in order: 1. Pregnancy testing 2. Contraception 3. Infertility	

Abbreviation: FDA, U.S. Food and Drug Administration.

[a] Several subsections follow, expanding upon the risk findings. In general, when human data are sufficient to assess the specific risk, standard language is required to indicate whether specific types of abnormalities are associated; when human data are available, but insufficient, the likelihood of the risk should be indicated; when animal data indicate the risk of a specific anomaly, a conclusion as to risk is required; and the last subsection includes a mandate for cross references to contraindications/warnings elsewhere on the label.

[b] Subsections that follow elucidate additional information to be contained about risk. In general, if no data are found of systemic absorption, a statement to that effect and assumption of no exposure to the nursling is made. If there is evidence of detection in milk, it must be so noted, as well as effects on child and milk production as well as the assay used, its limits, and a standard statement as to detection. When either the drug or active metabolites are detectable, the label also will include concentration in relationship to maternal/pediatric dose, an estimate of the maternal dose excreted, and an estimate of the consumption of a nursling based on average daily milk consumption. Another subsection must note pharmacologic and toxicologic information to identify known or predicted effects on the child, and pharmacokinetics related to amount and age will be included as they can affect the child. If only animal data are available, information regarding detection in animal milk and type of animal species is included. The last subsection includes a mandate for cross references to contraindications/warnings elsewhere on the label.

Based on U.S. Food and Drug Administration. Content and format of labeling for human prescription drug and biological products; requirements for pregnancy and lactation labeling. 79 FR 72063. *Federal Register.* 2014;79(9233 pt. 2):72064-72102. Accessed September 11, 2016.[62]

The pregnancy and lactation section has two important additions. First, this section includes

a *Fetal Risk Summary* subsection for all drugs that are absorbed systemically. This text summarizes what is known about each medication's embryocidal, teratogenic, and/or fetotoxic risks. This section also has an initial subsection titled *Pregnancy Exposure Registry* that provides contact information for a pregnancy registry, if one exists. Pregnancy registries are observational studies of the effects of drugs on pregnant women. These studies are critically important for gathering postmarketing information about the effects of drugs.[63,65] Pregnancy exposure registries are created and monitored by the drug manufacturer. The FDA does not administer these groups, but it may recommend or even require establishment of such an observational study by the manufacturer. Midwives should contribute data about untoward drug effects identified in practice to these registries to facilitate early detection of adverse drug effects.[63]

Pharmaceuticals Commonly Used During Pregnancy

The drug classifications most commonly used during pregnancy include vitamins, analgesics, antimicrobials, and blood glucose regulators. The sections that follow present a brief review of these categories of pharmaceuticals.

Analgesics

The category of *nonsteroidal anti-inflammatory drugs* technically includes acetaminophen, ibuprofen, and aspirin. In general use, the term NSAIDs refers specifically to the family of drugs similar to ibuprofen (Advil), which is how the term is used in this chapter. Aspirin and NSAIDs have been implicated in disruption of the prostaglandin cascade involved in initiation of labor and, therefore, are linked to post-term pregnancy. NSAIDs can cause premature closure of the ductus arteriosus; indeed, they are administered to neonates for that specific therapeutic effect.[66] Aspirin has been associated with fetal vascular disruptions as well as competition with bilirubin for albumin binding sites. NSAIDs and aspirin should be avoided in pregnancy, especially in the first and third trimesters. An alternative agent without anti-inflammatory action is acetaminophen (Tylenol).[67] Acetaminophen is the analgesic of choice for minor pain during pregnancy.

Opiate analgesics have not been implicated as having teratogenic effects. Caution with their use in pregnancy is based on fear of addiction, not teratogenicity.[35]

Antimicrobials

Penicillins and *cephalosporins* are among the most commonly prescribed antimicrobials for treatment of various female reproductive infections. Few studies of cephalosporins have been conducted in the first trimester of pregnancy, but no adverse effects have been reported and cephalosporins, like penicillin, belong to the beta-lactam classification of antimicrobial agents. However, because the penicillins and erythromycin have been studied extensively and not found to be associated with teratogenic effects, many experts advocate using them as first-line therapies whenever indicated.[68]

Metronidazole (Flagyl) is a well-established antiprotozoal agent and the treatment of choice for *Trichomonas vaginalis* infection and bacterial vaginosis. No teratogenic effect secondary to use of metronidazole has been confirmed. However, its mechanism of action involves bacterial mutation and the drug is carcinogenic in rodents, so many providers consider use of metronidazole contraindicated in the first trimester. Although evidence does not support withholding the drug,[69] the conditions for which it is used generally are not life threatening. Because metronidazole is the most effective drug for the treatment of trichomoniasis, it should be prescribed for women who are symptomatic. Metronidazole is not recommended for treatment of asymptomatic trichomoniasis or bacterial vaginosis for the purpose of decreasing the risk of preterm labor.

Quinolones are rarely used in pregnancy because animal studies have demonstrated drug accumulation in the joints with subsequent damage.[70] These drugs may not pose the same risk

to humans but until more data are available, they are not recommended for use during pregnancy.

Sulfonamides are not teratogenic but require attention to timing. These agents are highly protein bound and can displace bilirubin from binding sites. The most commonly used agents in this category are a combination of sulfamethoxazole and trimethoprim (Bactrim, Septa). Administration of sulfonamides becomes problematic when these agents are administered near the time of birth, because the free bilirubin that is displaced will be in the newborn's circulation. The immature liver is unable to compensate for this effect, and kernicterus may result from these high plasma levels. Thus, sulfonamides should be avoided in the third trimester. Sulfasalazine (Azulfidine) appears to be an exception; this sulfonamide is used primarily for the treatment of ulcerative colitis and Crohn's disease and has a weak effect (if any) on bilirubin.

Tetracyclines are contraindicated in pregnancy because they concentrate in teeth. Children exposed in utero to tetracyclines may have yellowed teeth with poor enamel and vulnerability to caries, as well as potential problems with bone growth.[68]

Aminoglycosides include streptomycin, gentamycin (Garamycin), and kanamycin (Kantrex). All are ototoxic drugs that can cause permanent eighth cranial nerve damage. These agents are reserved for grave situations in which their benefits outweigh their risks.

Drugs Used to Treat Medical Conditions During Pregnancy

Although midwives care independently for women without medical or obstetric complications, they often consult and collaborate in the care of women who experience these complications. Thus, knowledge of drugs that have teratogenic or fetotoxic effects and that are used in the care of pregnant women who have medical complications is necessary.

Anticonvulsants

Antiepileptic agents pose a distinct challenge to the healthcare provider. Seizure disorders themselves may contribute to teratogenic outcomes. Several older antiepileptic drugs (AEDs) are teratogenic, although the absolute risk of congenital malformations following prenatal exposure is low.[71] Phenytoin (Dilantin) is associated with midline cardiac defects, hypospadias, neonatal coagulopathy, and neurobehavioral impairment. Carbamazepine (Tegretol), valproate (Depacon), and valproic acid (Depakene) can cause a dysmorphic pattern of minor anomalies, including neural tube defects and midline cardiac defects. Valproate and valproic acid are associated with intellectual impairment, and the congenital anomalies related to these drugs appear to be dose dependent.[72] Phenobarbital (Solfoton) has been associated with neurobehavioral impairment and newborn withdrawal syndrome. Newborns exposed in utero to phenytoin (Dilantin), carbamazepine (Tegretol), or phenobarbital (Luminal) are at risk of coagulation problems secondary to drug-induced vitamin K deficiency, and need prompt supplemental vitamin K after birth. Newer-generation antiepileptic drugs such as gabapentin (Neurontin) and lamotrigine (Lamictal) do not appear to have teratogenic effects.[73]

Many mechanisms have been proposed to explain the teratogenicity of anticonvulsant agents. Several of these drugs appear to have antifolate characteristics, and some authorities recommend that women on AEDs should be treated with 4 mg of folic acid both prior to conception and in early pregnancy.[74] Working closely with maternal–fetal specialists when caring for a woman with a seizure disorder is necessary, as treatment requires the choice of the least risky drug, at the lowest dose that controls seizures.

Antidepressants

Antidepressants represent another drug category used by many women during pregnancy. The most widely used class of medications to treat depression, bipolar disorder, and anxiety disorders are the selective serotonin reuptake inhibitors (SSRIs), which include agents such as fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft).[75,76] Untreated depression is associated with several adverse pregnancy outcomes, including preterm birth, postpartum depression, and poor behavioral and mental health outcomes in children.[77] For this reason, treatment of depression during pregnancy is recommended.

Although knowledge about the teratogenic and fetotoxic effects of SSRIs and serotonin–norepinephrine reuptake inhibitors (SNRIs) is still being elucidated, midwives need to educate women on some effects linked to these drugs prior to initiating or continuing therapy during pregnancy. For example, paroxetine generally is avoided in pregnancy because of its potential for inducing fetal cardiac conditions.[76] Conversely, paroxetine and sertraline appear to have the best safety profile for women who are breastfeeding.[76,78] Midwives who choose to add these drugs to their individual formulary or who manage women who are taking these drugs must know the required screening and diagnostic criteria for depression and other related mental disorders, understand the side effects and adverse effects associated with these agents, appreciate the FDA's "black box" warnings for these drugs, and practice within a setting that provides access to psychiatric services. Because information related to these agents' use is rapidly increasing, professionals must keep abreast of any changes related to their recommended usage.

Antihypertensive Drugs

Antihypertensives are prescribed for women with chronic hypertension, a condition that may coexist with pregnancy. Chronic hypertension is defined as a systolic blood pressure of at least 140 mm Hg or a diastolic blood pressure of 90 mm Hg before pregnancy or in pregnant women prior to 20 weeks' gestation.[79,80]

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are contraindicated in pregnancy secondary to an increased risk for teratogenic effects. Use of these drugs in the second and third trimesters is associated with low birth weight, oligohydramnios, and hypoplastic fetal lung development.[79] Atenolol (Tenormin) has been associated with intrauterine growth restriction (IUGR) secondary to reduced placental function. This problem has not been noted following use of the other beta blockers; thus, with the exception of atenolol, beta blockers are the first-line drugs used to treat chronic

hypertension in pregnancy. Labetalol (Trandate) is the most commonly used antihypertensive prescribed in the United States today.[79]

The other category of antihypertensive drugs that appear safe in pregnancy is the calcium-channel blockers, which include agents such as nifedipine (Procardia). Nifedipine is also used as a tocolytic.

Hypoglycemic Agents

Hypoglycemic agents are another drug category of interest to midwives, given that the number of women with type 2 diabetes is increasing in the United States and these women typically use oral hypoglycemic agents when not pregnant. Untreated diabetes is associated with multiple adverse outcomes for both the pregnant woman and her fetus, most of which occur secondary to hyperglycemia. Therefore, close glucose control is essential during pregnancy.[81,82] Traditionally, women with preexisting type 2 diabetes who are pregnant are treated as though they have gestational diabetes and managed with diet, exercise, and injectable insulin. In contrast to oral hypoglycemic agents, insulin is a large molecule and has difficulty crossing the placenta. Therefore, for many years it has been the drug of choice for management of diabetes mellitus during pregnancy.[83]

Glyburide (Micronase, DiaBeta) and metformin (Glucophage) have recently been the subject of research for treatment of diabetes during pregnancy.[84,85] Glyburide is extensively protein bound and does not cross the placenta in sufficient amounts to affect the fetus. Both glyburide and metformin appear to be safe and effective when used to treat diabetes in pregnancy, but neither is fully endorsed or established in clinical practice as yet.[84-86]

Thyroid Drugs

Thyroid drugs are frequently used during pregnancy. The most common cause of hyperthyroidism is Graves' disease, which occurs secondary to the development of autoantibodies. These autoantibodies bind to the thyroid-stimulating hormone (TSH) receptor on the thyroid gland, which results in excessive production of thyroid hormone. Untreated hyperthyroidism has been linked to spontaneous abortion. The most popular treatment for hyperthyroidism is radioiodine (RAI), which is radioactive iodine that concentrates in the thyroid and destroys thyroid tissue. Radioiodine is contraindicated in pregnancy because it can cross the placenta and destroy the fetal thyroid. Traditionally, propylthiouracil (PTU) has been the drug of choice for hyperthyroidism in pregnancy, as methimazole (Tapazole) has been linked to aplasia cutis in the newborn. More recently, this neonatal association has been called into question.[87] Moreover, PTU may result in fetal hypothyroidism when the drug is used in high doses, so close monitoring is required when it is prescribed to a pregnant woman. Women who are taking PTU should be seen by an obstetrician to establish a plan for ultrasound monitoring to assess the fetal thyroid.

The most common etiology of hypothyroidism is Hashimoto's disease, also known as autoimmune thyroiditis. Untreated hypothyroidism can cause fetal mental retardation, preeclampsia, stillbirth, and other adverse obstetric outcomes.[88,89] Hypothyroidism is treated

with levothyroxine (Synthroid), which is synthetic thyroid hormone. Levothyroxine has no adverse effects on the fetus, but the maternal dose may need to be increased by as much as 45% during pregnancy; to confirm that the appropriate dose is being administered, TSH and free thyroxine (T_4) levels are typically assessed once each trimester. The goal is to maintain a euthyroid state during pregnancy.

Many practices are adopting universal screening for thyroid disorders in pregnancy, although questions have been raised about whether such screening makes a difference in perinatal outcomes. It has been associated with increased use of thyroid drugs.[89]

Conclusion

Pharmaceutical agents are part of modern life. Pharmacology is an essential area in women's health care, and one that continues to expand and challenge providers and women alike. Like any other intervention in a midwife's repertoire, drugs and herbs should be used appropriately and monitored for both therapeutic and adverse effects. Various publications, both in print and in electronic media, have emerged to help clinicians access current pharmacologic information. Prominent among these innovations are applications for smartphones that can download information about all FDA-approved medications, including doses, contraindications, cautions, interactions, adverse reactions, cost, and pregnancy categorization. Of course, such resources are useful only when they are updated and consulted regularly.

A single agent is rarely a magic cure for a woman independent of the larger context of her health, social, educational, economic, and other factors. No professional should simply prescribe or recommend any pharmaceutical product without taking such considerations into account. Viewing the woman and her needs holistically is one of the skills of a great midwife. As an ancient Chinese saying states, "It is easy to get a thousand prescriptions, but hard to get one single remedy."

PART III

Gynecology

PATRICIA AIKINS MURPHY AND FRANCES E. LIKIS

Patricia Aikins Murphy and Frances E. Likis

Today, the average life expectancy at birth for a woman who resides in the United States is 81.2 years.[1] Within this lifespan, the average woman wants two children, and thus spends about 3 years pregnant, postpartum, or trying to become pregnant. She will spend approximately 30 years—the vast majority of her reproductive life—trying to avoid pregnancy.[2] Moreover, given modern life expectancy, this woman will enjoy 3 or more decades of life after her reproductive years have ended.

Ideally, most of this woman's life will be spent in good health, where health, as defined by the World Health Organization (WHO), is a "state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity."[3] Ideally, she will also enjoy reproductive health at all stages of her life, defined by WHO as the ability "*to have a responsible, satisfying, and safe sex life and . . . the capability to reproduce; and the freedom to decide if, when, and how often to do so.*"[4]

Making these hopes for good health a reality requires health promotion, disease prevention, health education, and empowering women to make the choices that are meaningful to them and the choices that will optimize their health.

Fortunately, these are skills in which midwives excel. Add the recognition that life stages, normal physiology, and developmental processes are not diseases; that continuity of care is a value to be promoted; that informed choice, shared decision making, and the right to self-determination are important to health; and that evidence-based decision making should underlie the health care of women, and we have several of the hallmarks of midwifery important for providing gynecologic, sexual, and reproductive health care.[5] While midwifery is often associated with pregnancy and birth, women have healthcare needs at all stages of their lives that are not related to pregnancy. Thus, gynecologic, sexual, and reproductive care are, and

should be, essential aspects of midwifery practice that are well established in the American College of Nurse-Midwives (ACNM) Core Competencies,[5] where specific knowledge and skills of midwifery responsibilities beyond perinatal care are detailed in several sections.

Caring for women in the area of gynecologic, sexual, and reproductive health gives midwives the opportunity to truly be with women for a lifetime, from adolescence through old age. Most women spend only a few years of their lives needing maternity care services, but they need other healthcare services that midwives can provide for many more years. Although the face of U.S. health care can change with political imperatives and economic demands, the Health Resources and Services Administration has published Women's Preventive Services guidelines, the most recent iteration of which was released in 2016.[6] Under the prevailing insurance guidelines, women can currently receive annual well-woman visits, human papillomavirus testing, counseling for sexually transmitted infections, HIV screening, and contraceptive methods and counseling without paying a copayment, coinsurance, or a deductible (note that there are some exemptions for organizations that object to contraceptive counseling or provision).[6] Midwives must be poised and prepared to provide these services. The knowledge found in the chapters in this section provides the foundation for being "with women for a lifetime."[7]

CHAPTER

10

Anatomy and Physiology of the Female Reproductive System

TEKOA L. KING AND MARY C. BRUCKER

The editors acknowledge Ellen L. Tilden for contributions to this chapter. The editors acknowledge Jenifer O. Fahey, who was an author of this chapter in the previous edition.

Introduction

Midwifery practice begins with an understanding of reproductive anatomy and physiology. Four chapters in this text specifically focus on the anatomy and physiology underpinning clinical practice. This chapter provides a general overview of the anatomy of the female reproductive system, including the breast, and describes basic reproductive physiology, including menstrual physiology. The *Anatomy and Physiology of Pregnancy* chapter reviews maternal anatomic and physiologic adaptations to pregnancy and fetal and placental development and function. The *Anatomy and Physiology During Labor and Birth* chapter focuses on the processes involved in labor and birth. The *Anatomy and Physiology of Postpartum* chapter describes the physiology of the puerperium. Other chapters also include information on important physiologic processes. The physiology of lactation, for example, is described in the *Breastfeeding and the Mother–Newborn Dyad* chapter, while the transition of the newborn to extrauterine life is covered in the *Anatomy and Physiology of the Newborn* chapter.

The Breast

The breast undergoes dramatic changes in size, shape, and function during a woman's lifetime. Growth, differentiation, and lactogenesis are the result of complex hormonal stimuli. Breast development starts during embryonic life. Full development of breast tissue takes place during pregnancy and lactation.

Breast Anatomy

The adult female breast extends vertically from approximately the second rib to the sixth rib, and horizontally from the edge of the sternum to the mid-axillary line with an extension of tissue into the axilla known as the tail of Spence (**Figure 10-1**).[1] Breast tissue is composed of skin, subcutaneous tissue, and breast tissue. The nipple, which is located slightly below the center of each breast, is surrounded by a circular area of pigmented skin known as the areola. The shape of the breast is maintained primarily by suspensory ligaments, known as Cooper's ligaments, that connect the dermis of the breast to the deep pectoral fascia, which overlays the pectoralis major and serratus anterior muscles of the chest.

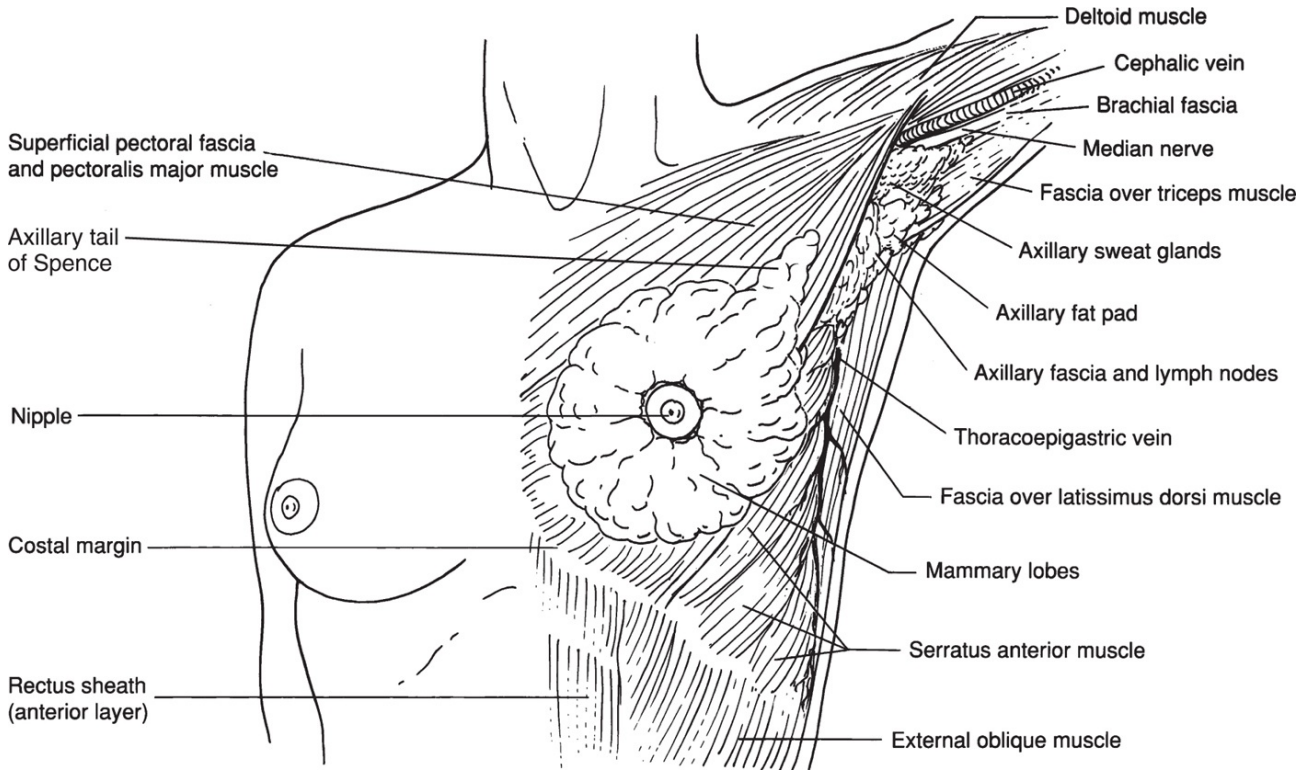

Figure 10-1 Anterior pectoral dissection.

Modified with permission from Clemente CD. *Anatomy: A Regional Atlas of the Human Body*. 6th ed. Philadelphia, PA; 2011.[1] Reprinted by permission of the author.

The skin of the breast includes the nipple and the areola, the area that surrounds the nipple. The nipple's elastic tissue contains smooth muscle fibers and is innervated by both sensory and autonomic nerve endings. The nipple becomes smaller and firmer in response to cold, touch, and sexual stimulation under the influence of oxytocin. The darker circular areola surrounding the nipple is somewhat elastic and varies in diameter.

The nipple has approximately 5 to 9 mammary ductal orifices and is abundantly innervated with sensory nerve endings. The nipple/areola complex has many sebaceous and apocrine sweat glands. For example, the Montgomery glands are large sebaceous glands located under the areola. The openings to these glands form round elevations just under the skin of the areola, called Montgomery tubercles. The Montgomery glands become enlarged in pregnancy; they produce secretions that keep the nipple/areola complex lubricated and may assist in the initiation of lactation by providing olfactory cues to the newborn. A more detailed description of lactogenesis can be found in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

The breast tissue is composed of epithelial (glandular or secretory) tissue, between which is interspersed stromal (adipose and connective) tissue. These two types of tissue are present in approximately equal amounts in the breasts of women who are not pregnant or lactating.[2] During pregnancy and lactation, however, the glandular tissue proliferates and becomes the predominant breast tissue.[3] Postmenopausally, the glandular tissue tends to shrink and is generally replaced by fat, resulting in changes in shape and size.

The glandular tissue in each breast of a reproductive-age woman is organized into several lobes that are made up of clusters of 10 to 100 alveoli, referred to as lobules (**Figure 10-2**). Traditionally, the lobes have been depicted as separate, distinct entities that terminate in a lactiferous sinus just under the nipple.[2] More recently, some controversy has arisen regarding the structure of the breast ductal system. First, the lactiferous sinus may not be an anatomic structure per se, but rather a transient dilation of the terminal duct that occurs during lactation.[2] A few studies have found anastomoses between lobes, while others have not found anastomoses; the majority, however, have shown that each ductal system is independent.[4] Because breast cancer forms in ductal systems, a thorough understanding of this anatomy has important clinical implications.

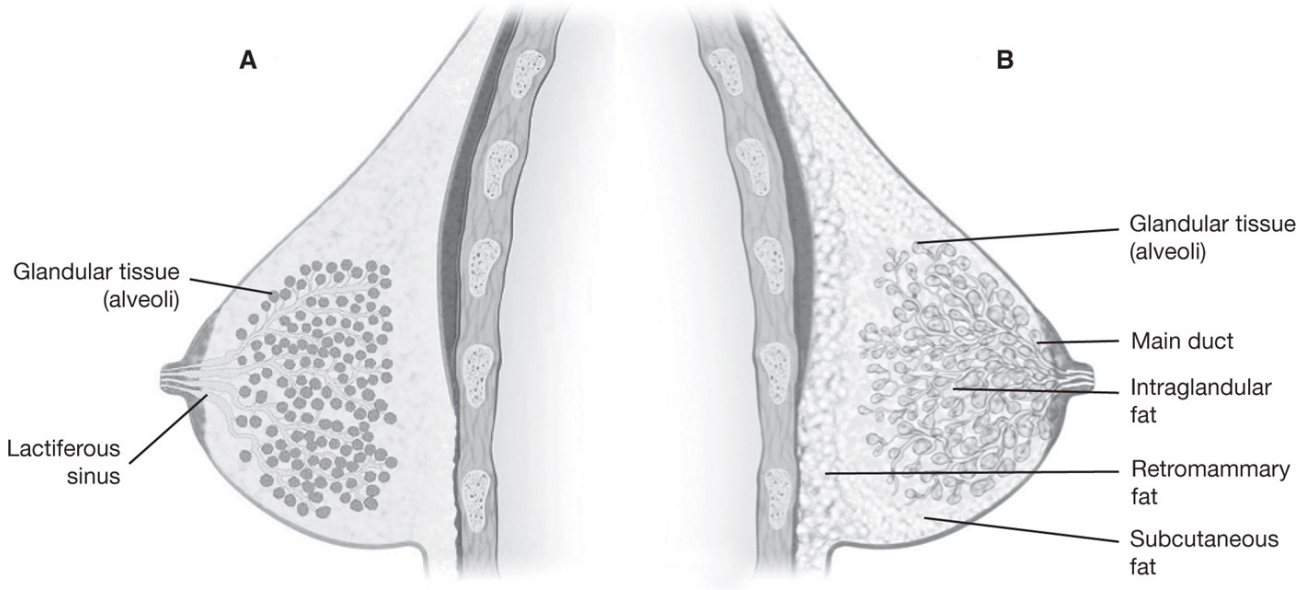

Figure 10-2 **A.** Traditional schematic diagram of the anatomy of the breast. The main milk ducts below the nipple are depicted as dilated portions or lactiferous sinuses and the glandular tissue is deeper within the breast. **B.** Schematic diagram of the ductal anatomy of the breast based on the findings of Ramsay et al.[3] Milk ducts are small and branch a short distance from the base of the nipple. The ductal

system is erratic and glandular tissue is situated directly beneath the nipple.

The alveoli are dilated sac-like structures composed of two layers of cells. The inner luminal cells are responsible for synthesis and secretion of breast milk. They are surrounded by myoepithelial cells that eject milk during lactation (**Figure 10-2**). During pregnancy, the alveoli gain the capacity to produce and excrete milk. These differentiated alveoli are referred to as acini. The secretory cells in these acinar units are stimulated by prolactin to secrete milk into the lumen of the alveolus, whereas the myoepithelial cells are stimulated by oxytocin to contract, which compresses the alveolar sacs so that milk is ejected into the milk ductules. The ductules are connected to larger lactiferous ducts, which merge to form a smaller number of ducts leading to openings at the nipple, through which milk exits the breast. The exact number of these openings is not known, but has been reported to vary from 4 to 18; however, the most recent evidence seems to suggest that there are, on average, 5 to 9 patent ducts in each nipple of a lactating woman.[3]

Blood is supplied to the breast primarily by the mammary artery and by the lateral thoracic arteries. Venous flow from the breast drains into the internal thoracic, axillary, and cephalic veins. The lymphatic vessels of the breast serve an important function during lactation by draining milk molecules that are too large to move into blood vessels.

Lymphatic flow to and from the breast is significant because it determines the location of metastasis of cancer cells from the breast to other parts of the body. The majority of breast lymph flows to the axillary lymph nodes, which is, therefore, the main route of cancer metastasis from the breast. The intermammary lymph nodes are the other main group of lymph nodes that drain the breast, but they receive only a small fraction of the lymph flow from the breast.

The breast is innervated by the lateral and anterior cutaneous branches of the second to the sixth intercostal nerves and by the supraclavicular nerves. The nipple and areola are innervated primarily by the cutaneous branch of the fourth intercostal nerve.

Breast Development

Human breast development begins during the embryologic period and is believed to originate with the appearance of the primitive milk streaks bilaterally in the embryo from the axilla to the groin. This ridge regresses except for the region that eventually becomes the mammary gland. On occasion, additional areas of this ridge may not regress; these areas then develop into accessory nipples and sometimes even into glandular mammary tissue capable of milk production and excretion. Such auxiliary nipples may be noted on a physical examination, but have no clinical significance.

At birth, newborns have an opening of a primitive ductal system to the surface, a protruding nipple, and a circular area of skin that has proliferated into the areola. Varying degrees of glandular breast tissue development occur during the fetal period. At birth, the structures present can range from simple blunt-ended tubular structures to well-developed branching ductal systems with lobular–alveolar structures.[5] Under the influence of maternal and neonatal pro-lactation hormones, these structures are capable of producing milk shortly after birth. In

some cases, this milk is excreted and exits via the neonate's nipple (sometimes referred to as "witch's milk"). Once the maternal hormones are removed, however, the infant breast tissue undergoes a period of involution. By the time the child reaches 2 years of age, only a small ductal system remains. Some growth in this tissue is noted during childhood, but no development occurs until puberty, when the female breast undergoes a period of extensive development.

With the onset of puberty, a process of elongation and branching of the ductal system begins, along with formation of lobules through development of some of the ductal endings into clusters of ductules and alveolar buds. This gradual process of branching and lobule formation occurs primarily under the influence of estrogen, but actually involves multiple hormones, including growth hormone. In the adult woman, some of these lobules will undergo further branching and glandular development with each menstrual cycle. However, full glandular differentiation and formation of the secretory acini capable of producing and secreting milk do not occur until pregnancy. The changes in breast structure that take place in pregnancy and lactation are referred to as mammogenesis and lactogenesis. Both processes are detailed in the *Anatomy and Physiology of Pregnancy* and *Breastfeeding and the Mother–Newborn Dyad* chapters, respectively. Following lactation, the breast glandular tissue undergoes regression and atrophy with tissue remodeling. The breast tissue atrophies further after menopause, with the number of lobes decreasing and fibrous connective tissue and adipose tissue accumulating during this phase of the life span.

The External Female Genitalia

The external female genitalia, also referred to as the vulva, are those structures located between the pubis and the perineum. They include the mons pubis, the labia minora, the labia majora, the clitoris, the hymen, the vestibule, and the urinary meatus or urethral opening. Although not externally visible, the Bartholin glands and Skene's glands and ducts as well as the vestibular bulbs are also considered part of the external female genitalia.

The mons pubis is the layer of fatty tissue that overlays the pubic bone. In the postpubertal woman, the skin of the mons is covered with coarse, curly hair. The labia majora are folds of connective and adipose tissue that extend inferiorly from the mons and merge posteriorly into the perineal body to form the posterior commissure. Medial to the labia majora are the labia minora, which are two thin folds of connective tissue. The area between the labia minora that extends from the clitoris to the fourchette is referred to as the vestibule and is the area into which the urethra, the ducts of the Bartholin glands, the vagina, and, sometimes, the Skene's ducts open. The labia minora merge superiorly to form the prepuce and frenulum of the clitoris and inferiorly to form the fourchette. Prior to a vaginal birth, both the labia majora and the labia minora assist in keeping the vaginal introitus closed and in protecting the urethral opening. In multiparous women, the labia minora may project beyond the labia majora; in contrast, in nulliparous women, the labia minora are usually not visible unless the labia majora are separated.

After menopause, pubic hair tends to thin and gray. The vulva also may thin and flatten, losing some of its fullness.

Clitoris

The clitoris is a highly innervated, erectile organ located in the superior portion of the vestibule where the labia minora fuse. It is often described as the homologue of the penis. Unlike the penis, however, the function of the clitoris is purely erogenous. The clitoris has both internal and external portions that include a glans, prepuce/hood, corpus, suspensory ligament, root, and vestibular bulbs (**Figure 10-3**).[6] The glans, which is approximately 1.5 to 2.0 centimeters in length, is the visible portion of the clitoris. The two crura are composed of erectile tissue that creates an inverted V structure attached to the pubic arch and extending along the ischiopubic rami. Adjacent to the crura and flanking the vaginal orifice are the vestibular bulbs, which are also composed of vascular, erectile tissue. These structures become engorged with blood during sexual arousal. The root of the clitoris is located just behind the glans; it is where all the erectile tissue merges.

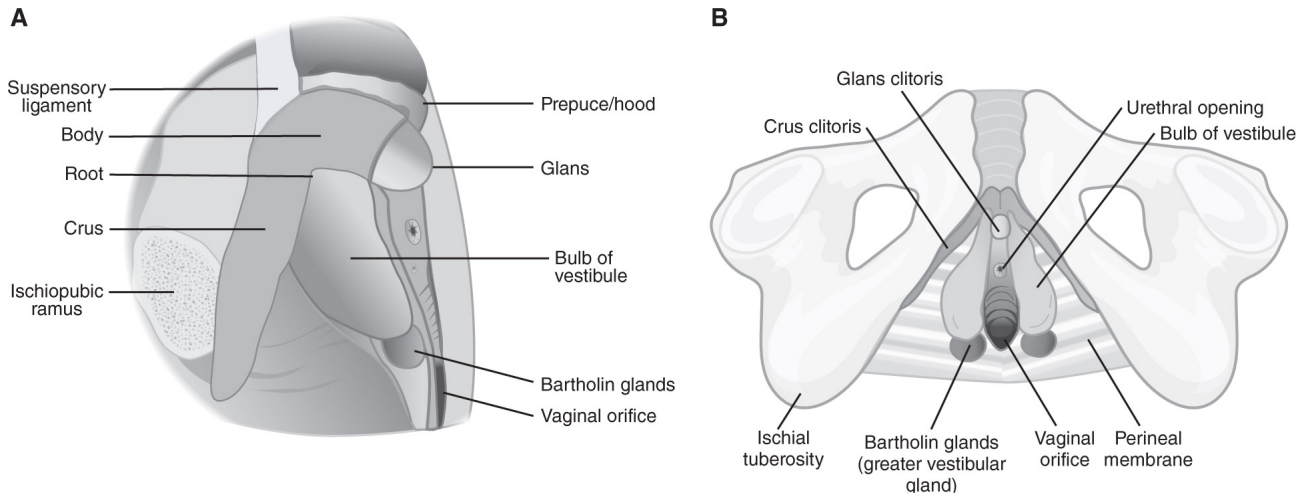

Figure 10-3 **A.** Lateral view of the clitoris and adjacent anatomy. **B.** Inferior view of the clitoris in relation to the urethra, vaginal orifice, and pelvic bones.

The clitoris is attached to the pubic symphysis by the suspensory ligaments. This organ is innervated by the dorsal nerve of the clitoris, branches of the pudendal nerve, and cavernous nerves that supply the erectile tissue arteries.

Although female sexual response may not be exclusively associated with clitoral stimulation, the clitoris is considered the center for orgasmic response.

Bartholin Glands and Skene's Glands

The Bartholin glands, which are also known as the major or greater vestibular glands, are located beneath the fascia of the vestibule on either side of the vaginal opening at about the 4 o'clock and 8 o'clock positions. Each gland has a duct that opens into the inferior part of the vestibule between the labia minora and the hymen. These glands secrete mucus during sexual arousal.

The Skene's glands, which are also known as the lesser vestibular glands or the periurethral glands, usually open onto the vestibule on either side of the urethra, but sometimes open on the posterior wall of the urethra. These glands also secrete mucus during sexual stimulation and/or arousal. Blockage of the Bartholin or Skene's glands can cause abscesses or cysts.

The Internal Female Genitalia

Figure 10-4 shows a midsagittal view of the internal organs and associated structures that make up the female reproductive system.[7] These organs and structures include the vagina, uterus, cervix, fallopian tubes, and ovaries. A detailed description of each component follows.

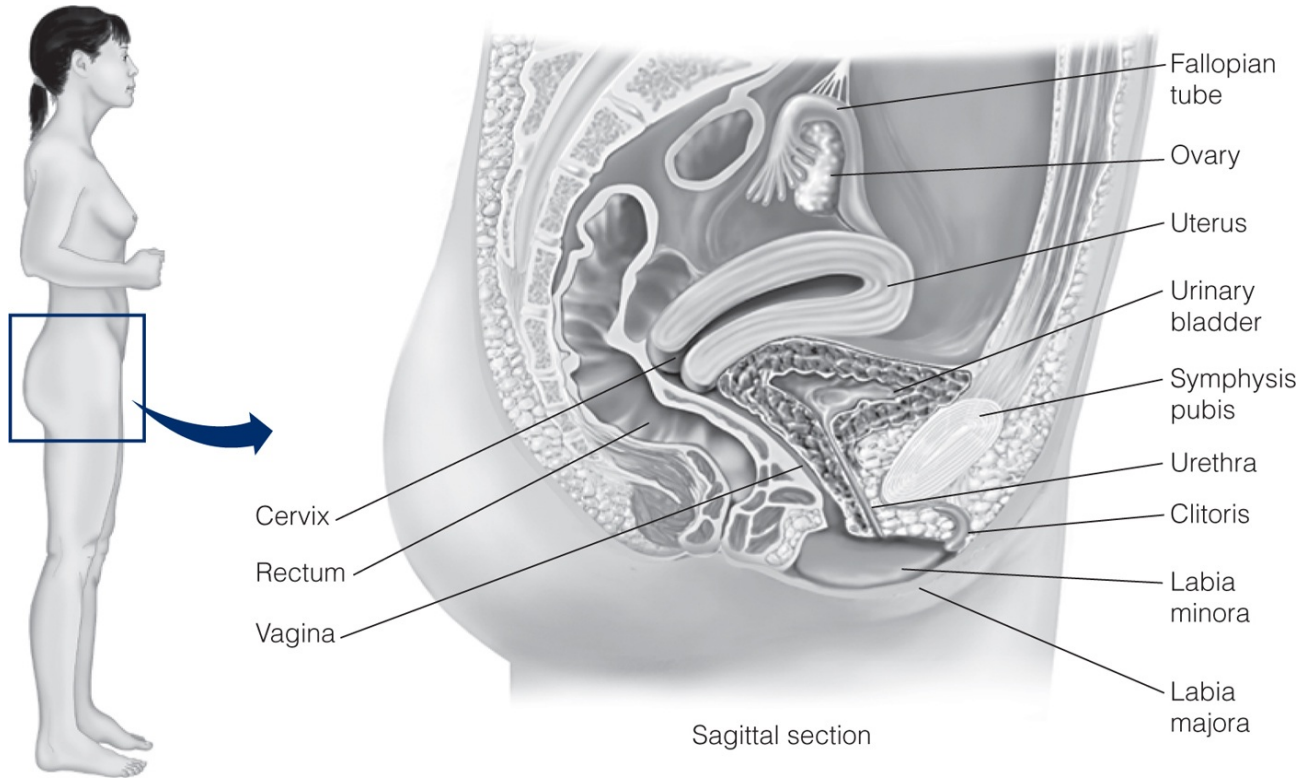

Figure 10-4 Midsagittal view of a woman's pelvis.

The Vagina

The vagina is a muscular structure extending from the vulva to the cervix. It is a potential space, in that the walls are usually in opposition, but can be separated to form a tube during intercourse or childbirth. Anteriorly, the vagina is separated from the bladder by connective tissue known as the vesicovaginal septum. Posteriorly, the vagina is separated from the rectum by the rectovaginal septum (in the lower segment) and by the rectouterine pouch or cul-de-sac of Douglas (in the upper segment). The walls of the vagina, which are referred to as the anterior, posterior, and lateral vaginal walls, run from the vaginal opening at the vestibule to the cervix posteriorly, where they create a "dead end." The spaces created between the cervix and the ends of the vaginal walls are called the fornices. There are four fornices: the anterior fornix, the posterior fornix, and two lateral fornices.

The vagina has three layers: mucosa, muscularis, and adventitia. The vaginal mucosa is lined with a layer of stratified squamous epithelium, which in premenopausal women is folded

into ridges known as rugae that can stretch and provide distensibility to the vagina. Beneath this lining is a layer of smooth muscle. The outermost layer of connective tissue, referred to as the adventitia, is contiguous with the visceral endopelvic fascia. These layers maintain vaginal tone. Postmenopausally, the vaginal walls become thinner, the rugae less apparent, and elasticity and moisture lessen.

The blood supply to the vagina emerges from the vaginal artery, which branches from the uterine artery, or directly from the internal iliac artery, the inferior vesical arteries, and the middle rectal and internal pudendal arteries. Blood is drained from the vaginal area by a venous plexus that follows the arteries, and lymph is drained primarily via the inguinal lymph nodes.

The vagina is innervated primarily by the uterovaginal plexus, which arises from the inferior hypogastric or pelvic plexus. This latter structure contains sympathetic efferent fibers from the second, third, and fourth sacral nerves. In addition, the vagina is innervated by a few filaments from the first two sacral ganglia. The lower two-thirds of the vagina is primarily innervated by the pudendal nerve.

The Uterus

The uterus is a pear-shaped, muscular organ that, in the nonpregnant state, is situated in the pelvic cavity superior to the urinary bladder. The uterus, a potential space for the nonpregnant woman, is anchored in place, usually—but not always—in an anteverted position, by the uterine ligaments. The adult nulliparous uterus measures approximately 6 to 8 centimeters in length, 5 centimeters across, and 4 centimeters in thickness; it weighs approximately 50 grams. The functions of the uterus include receiving a fertilized ovum, providing the environment for the embryo and the fetus, and contracting to help in the expulsion of the fetus and placenta.

The uterus has two main parts: the corpus (also called the body) and the cervix. During pregnancy, the body of the uterus differentiates into an upper segment called the fundus and a lower segment called the isthmus (**Figure 10-5**).

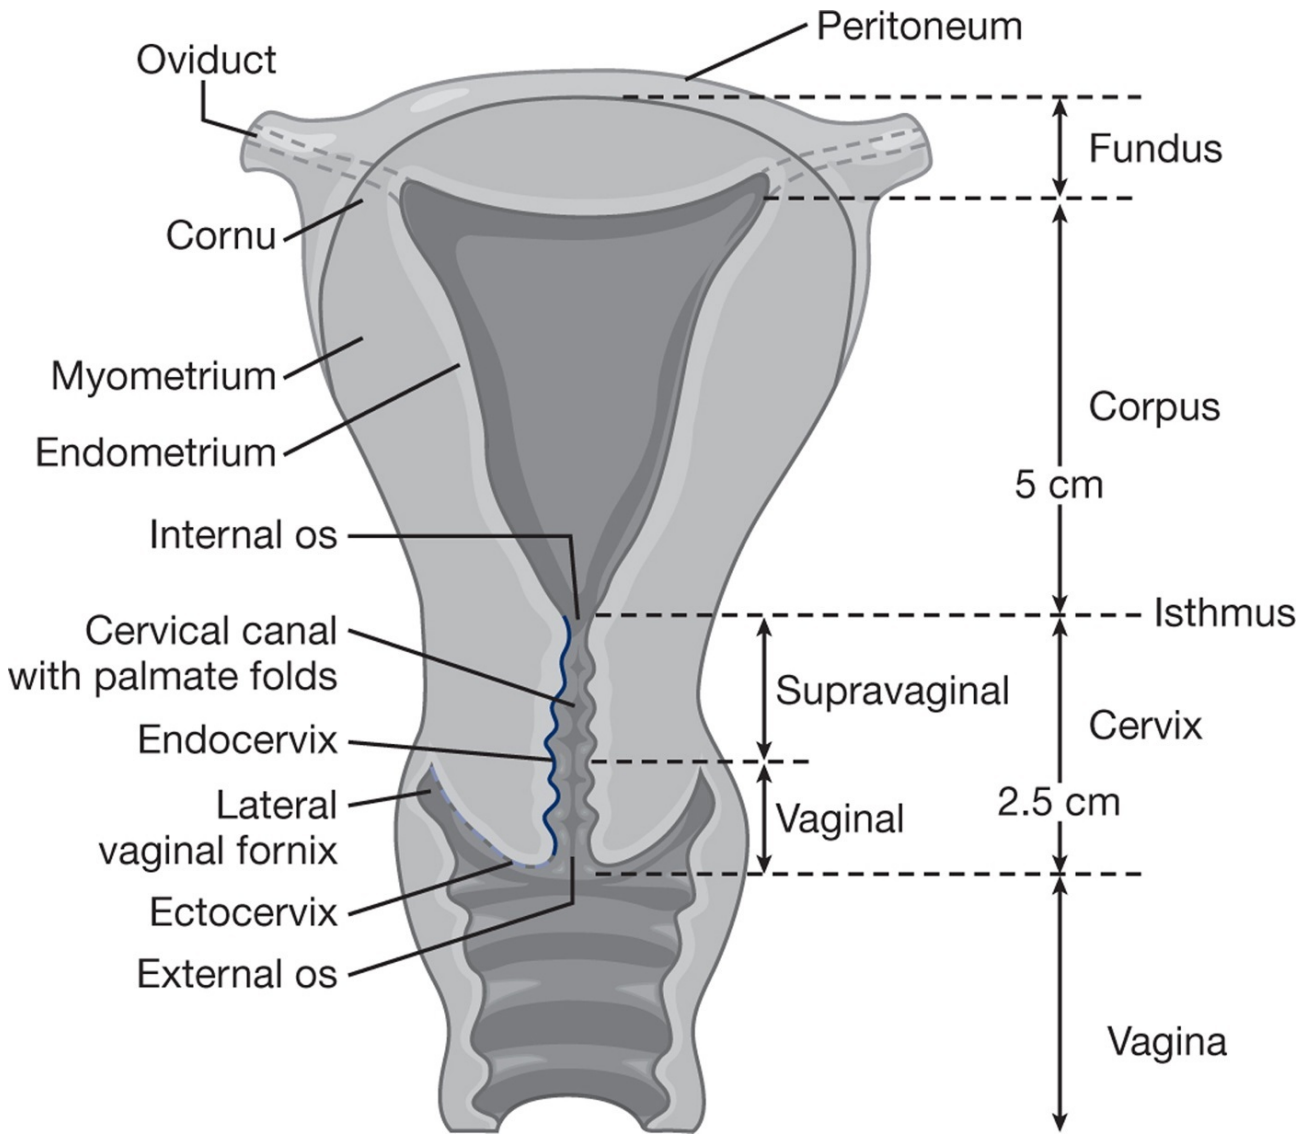

Figure 10-5 Frontal view of uterus.

The Uterine Body

The body of the uterus is made up of an external serosal layer formed by the peritoneum, a muscular (myometrial) layer, and a mucosal (endometrial) layer (**Figure 10-5**).

Endometrium

The endometrium is the mucosal lining of the uterine cavity. It is composed of (1) ciliated columnar epithelial cells; (2) glands that secrete a thin alkaline mucus rich in proteins, sugars, and secretions that allows survival of the zygote and blastocyst before implantation; and (3) the mesenchymal stroma, a layer of connective and vascular tissue that lies between the epithelial layer and the myometrium. This stroma can be subdivided into two layers: (1) the stratum basalis, which is closest to the myometrium and is not shed during menstruation, and (2) the stratum functionalis, the layer of the endometrium that proliferates and degenerates cyclically in menstruating women.

The endometrium receives blood from two different sets of arteries: a “straight” set of arteries that supply the stratum basalis and a set of “coiled” spiral arterioles that supply the stratum functionalis (**Figure 10-6**).[8] During the menstrual cycle, these vessels and the rest of the endometrium undergo marked changes. As part of the proliferative phase of the menstrual cycle, under the effects of rising levels of estrogen and progesterone, the endometrium becomes increasingly vascularized and the glands of the endometrium become longer and increasingly convoluted and fill with secretions. As a result, there is a 10-fold increase in thickness of the myometrium during the proliferative phase, from 0.5 to 5 millimeters.

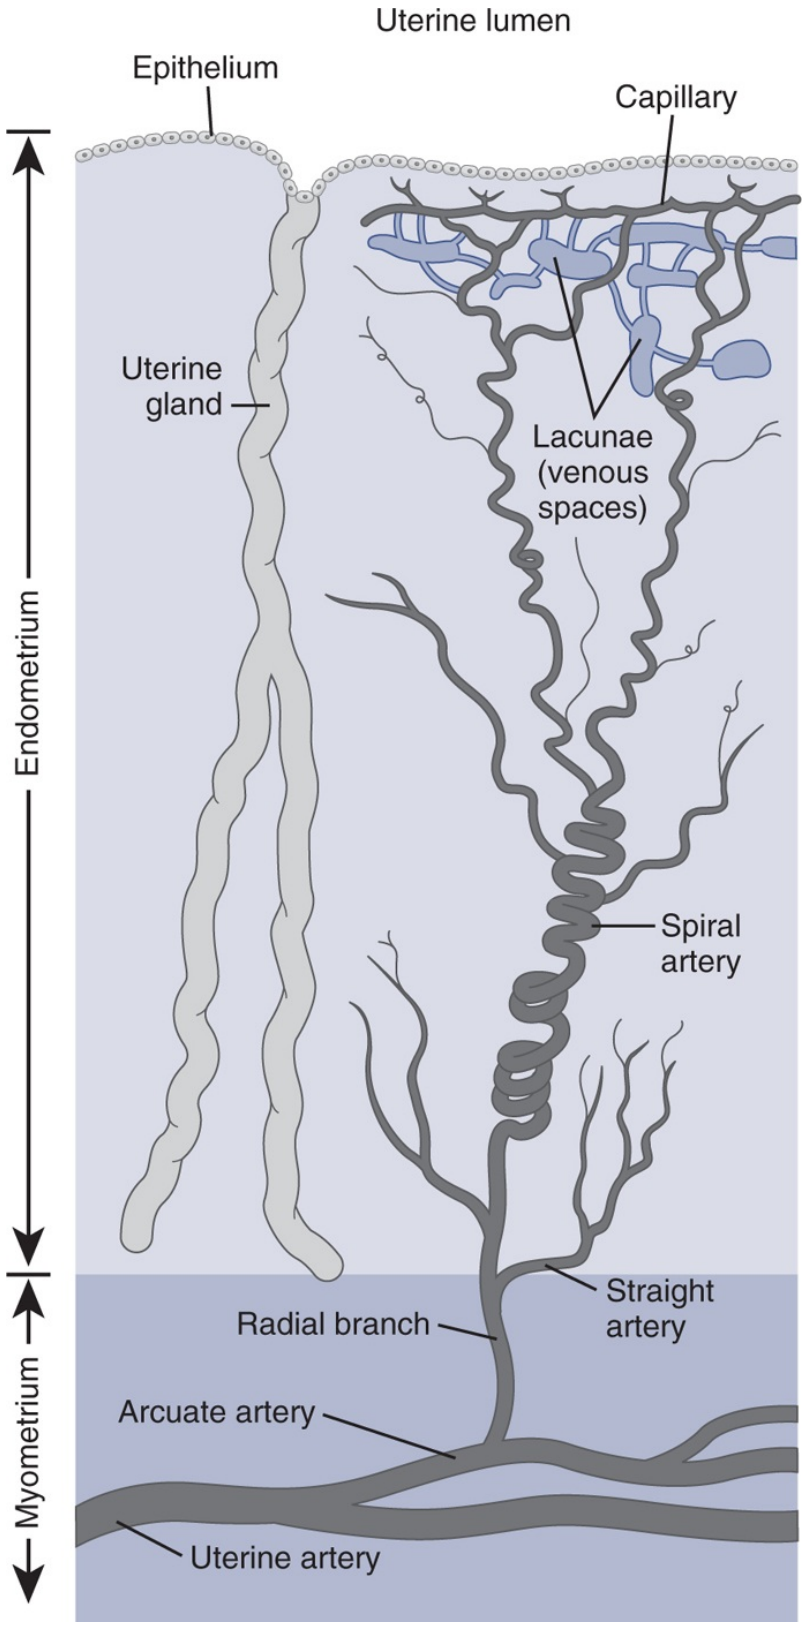

Figure 10-6 Anatomy and circulation of the endometrium.

If fertilization and implantation do not occur, the subsequent drop in estrogen and

progesterone levels leads to atrophy of the functional layer of the endometrium, which in turn leads to increased coiling of the spiral arterioles and a regression of the glandular development. The excessive coiling of the spiral arterioles diminishes the blood flow to the endometrial layer, which then produces tissue ischemia, necrosis, and endometrial bleeding. Menstrual flow is the result of this bleeding and shedding of necrotic endometrial tissue. A more detailed description of the menstrual cycle appears later in this chapter.

Once a woman has reached menopause, the endometrium becomes atrophic. The epithelium flattens, the glands gradually disappear, and the endometrial stroma becomes increasingly fibrous. In some cases, however, the endometrium may retain a weak proliferative capacity, which may contribute to the development of endometrial hyperplasia and perhaps ultimately endometrial cancer.[9]

Myometrium

The bulk of the uterus is made up of the myometrium, which is composed of bundles of smooth muscle fibers separated by connective tissue made primarily of collagen and elastin. The muscle fibers of the myometrium are arranged in three distinct patterns that contribute to this tissue's ability to contract effectively. In the inner layer of the myometrium, the fibers run in a circular pattern that spirals in a perpendicular orientation to the long axis of the uterus. In the middle layer, the muscle fibers are interlaced and form figure-eight patterns running diagonally along the long axis of the uterus.[10] The outermost layer of the myometrium contains an arrangement of fibers in both longitudinal and spiral patterns. These layers become more differentiated in pregnancy with the hypertrophy of the myometrial cells that occurs in pregnancy. Changes in the uterus during pregnancy are discussed in the *Anatomy and Physiology of Pregnancy* chapter, and the *Anatomy and Physiology During Labor and Birth* chapter contains a detailed description of the physiology of uterine contractions.

A gradient in the amount of muscle tissue found throughout the uterus is apparent, such that at the fundus, the myometrium contains primarily muscle fibers, whereas only 10% to 15% of the tissue mass in the cervix is composed of muscle fibers. The proportion of muscle fibers present determines the contractile strength of the uterine muscle, so this distribution of muscle creates a contraction strength gradient along the length of the uterus.

Uterine Ligaments, Blood Supply, and Innervation

The broad ligaments of the uterus are composed of folds in the peritoneum. These two wing-like structures extend from the sides of the uterus to the pelvic sidewalls. The superior part of the broad ligaments forms the suspensory ligament of the ovary and the mesosalpinx (to which the fallopian tubes are attached). The round ligaments attach on either side of the uterus just below and in front of the insertion of the fallopian tubes; they then cross the broad ligament in a fold of peritoneum, pass through the inguinal canal, and insert in the anterior (upper) portion of the labia majora on either side of the perineum. The ligaments are composed largely of smooth muscle that is continuous with the smooth muscle of the uterus. The round ligaments hypertrophy during pregnancy and stretch as the uterus enlarges. The peritoneal ligaments

(uterosacral, cardinal, and pubocervical) extend from the cervix to different parts of the pelvis and help to stabilize the uterus.

The vessels that supply the uterus are derived primarily from the uterine and ovarian arteries. The uterine artery is a branch of the anterior branch of the internal iliac arteries (also referred to as the hypogastric arteries). The uterine artery enters the side of the uterus through the broad ligament and divides into several branches supplying the lower cervix and upper vagina, the upper portion of the cervix, and the body of the uterus. One large branch of the uterine artery travels along the margin of the uterus toward the fundus. At approximately the height of the round ligament, this branch of the uterine artery furcates into three vessels. One vessel joins the terminal branch of the ovarian artery, one supplies part of the fallopian tube, and one supplies the uterine fundus. The vessels that supply and drain blood from the uterus are collectively referred to as the arcuate vessels of the uterus.

The ovarian artery is a direct branch of the aorta that enters the broad ligament. The main stem of the ovarian artery travels near the mesosalpinx (the part of the broad ligament that encloses the fallopian tubes) all the way to the upper, lateral portion of the uterus to join with the ovarian branch of the uterine artery. Branches from this main stem perfuse the ovaries and fallopian tubes.

The arcuate uterine veins that compose the uterine venous plexus join to form the uterine vein, which empties into the internal iliac vein. The blood from the upper and outer parts of the uterus and ovaries is collected by multiple veins that form the pampiniform plexus, draining into the ovarian vein. The right ovarian vein empties into the vena cava, while the left ovarian vein empties into the left renal vein. Lymph from the body of the uterus is drained by lymph vessels that carry their contents to either the internal iliac nodes or the periaortic nodes. The periaortic nodes also receive lymphatic drainage from the ovaries.

The parasympathetic system innervates the uterus via branches arising from the second, third, and fourth sacral nerves. In addition, the uterus receives some innervation from the sympathetic nervous system by the presacral nerve and lumbar sympathetic chain.

The Cervix

The cervix is the cylindrical, fibromuscular lower portion of the uterus that is sometimes referred to as the neck of the uterus. It has two areas of constriction at each end: the internal os, which is found at the junction of the cervix and uterine body, and the external os, which opens into the vagina. The role of the cervix and the cervical ora in pregnancy and birth are additionally reviewed in the *Anatomy and Physiology of Pregnancy* and *Anatomy and Physiology During Labor and Birth* chapters.

The cervix is composed primarily of subepithelial stroma, along with a smaller proportion of smooth muscle fibers.[11] The subepithelial stroma is approximately 80% collagen and ground substance, which contains blood vessels, nerves, and glands that secrete thick mucus. Elastin (a different protein than collagen) is present in smaller amounts but appears to play an important role in cervical remodeling during pregnancy, in labor, and after birth.[11] Recent studies have found that smooth muscle lies in a circular pattern around the internal os.[12] This tissue is not a classic sphincter, but may play a role in the cervical remodeling that occurs

during early labor.

The tunnel-like area between the internal and external os is called the cervical canal. The external surface of the cervix, known as the ectocervix, is lined with squamous epithelial cells like those lining the vagina. In contrast, the inner canal of the cervix, known as the endocervix, is lined with glandular epithelial cells, also termed columnar epithelial cells.

The area where the endocervix and exocervix meet is known as the transformation zone or the squamocolumnar junction; metaplasia begins here. It is in this region where most cervical cancers originate—which explains why obtaining a sample of these cells during a Pap test is important. Based on several factors such as age, pregnancy status, or hormonal contraceptive use, the squamocolumnar junction may be more or less apparent. When the columnar cells are visible, this benign condition usually is known as ectopy or eversion. In years past, eversion was sometimes termed erosion or ulceration, but this is a misnomer. A prepubescent female has a pink, smooth cervix without eversion. Women using hormonal contraception or who are pregnant often have marked eversion. As a woman ages, the cervical canal tends to recede and the squamocolumnar junction often is not visible.

The Fallopian Tubes

The two fallopian tubes, also referred to as oviducts and salpinges, are the 8- to 14-centimeter-long, narrow, muscular tubes that extend from the uterine horns or cornua. The oviducts, as their name would imply, transport the ovum from the ovary to the uterus. It is also in the fallopian tubes that fertilization normally takes place. The fallopian tubes have three layers: (1) the mucosa, a single-layer lining of ciliated or secretory columnar cells; (2) the muscularis layer; and (3) the serosa, the outer covering of the tubes, which is derived from the visceral peritoneum.

The fallopian tubes can be divided into four sections:

- The pars interstitialis is the portion of the tube that penetrates the muscular wall of the uterus and connects the cavity of the oviduct with the uterine cavity.
- The isthmus is the narrow segment that extends from the uterus.
- The ampulla is a wider segment of the oviduct and is where fertilization of the ovum most commonly occurs.
- The infundibulum is the fimbriated, open distal end of the fallopian tube.

The fimbriae are fine, fingerlike mucosal projections at the end of the fallopian tube that sweep near the ovaries, but are not connected to the ovaries. As a consequence, the oviducts open directly into the abdominal cavity. The fallopian tubes vary in diameter at the different segments, with the isthmus measuring approximately 2 to 3 millimeters in thickness while the ampulla reaches a diameter of 5 to 8 millimeters.

The structure of the oviducts promotes movement of the ovum from the ovary into the tubes and down toward the uterine cavity. The cilia of the mucosa move in waves to assist with transport of the ovum, and the fibers of the muscularis layer are arranged so that the oviducts may move and contract in a way that promotes transport of the ovum.

The Ovaries

The ovaries are the organs of gamete production in the female. In addition to producing ova, the ovaries manufacture the steroid hormones estrogen and progesterone and, therefore, are also part of the endocrine system. The two ovaries, which are almond shaped, vary in size from each other, from woman to woman, and in the same woman in different stages of her life. During the reproductive years, the ovaries measure, on average, 2.5 to 5 centimeters in length, 1.5 to 3 centimeters in width, and 0.6 to 1.5 centimeters in thickness. These organs are located in the upper part of the pelvic cavity. Each is attached in three ways: (1) to the broad ligament by the mesovarium; (2) to the uterus by the utero-ovarian ligaments, which extend from below the insertion points of the fallopian tubes in the posterior part of the uterus; and (3) to the pelvic wall by the suspensory ligament of the ovary (also referred to as the infundibulopelvic ligament). The suspensory ligament of the uterus is a fold of the peritoneum that extends from the ovary to the pelvic wall. This fold also contains blood vessels and nerves that supply the ovary.

Each ovary is made up of two main parts: the cortex and the medulla. The cortex—the outer layer of the ovary—is composed of connective tissue and contains follicles at different stages of development. It is lined with germinal epithelium, and its dull and whitish outer layer is referred to as the tunica albuginea. The medulla of the ovary also consists of connective tissue and contains arteries, veins, and smooth muscle fibers.

Two primary glandular cells within the ovarian follicles are involved in the synthesis of steroids: the thecal cells and the luteal (or granulosa) cells. Theca cells differentiate from the interfollicular stroma of ripening follicles in response to proteins secreted by growing follicles.[13] These cells produce the androgen substrate required for ovarian estrogen biosynthesis.

Ovarian Development

The human gonads are derived from three types of embryonic tissues: (1) coelomic epithelium, (2) mesenchyme, and (3) primordial germ cells. The primordial germ cells, which eventually will produce the gametes, originate in the yolk sac of the developing embryo. Until approximately 4 weeks' gestation, no sexual differentiation occurs in the development of the gonads. However, once the sex-determining region of the Y gene becomes activated, the process of sex differentiation begins.[14] Whereas development of the male reproductive system relies on activation of this gene and the effects of specific hormones, the development of the ovaries and female genitals follows the "default" process that happens in the absence of these hormones. For example, in the absence of testosterone, the Wolffian structures (which in the male embryo will become the male internal genitalia) regress. Similarly, the Müllerian ducts, without suppression from Müllerian-inhibiting hormone from the fetal testes, continue to develop and become the uterus, the oviducts, and the upper part of the vagina.

The ovaries develop from the coelomic epithelium, which proliferates to form the medulla and the cortex by the third month of gestation. The primordial germ cells in these fetal ovaries undergo rapid division and then differentiate into primary oocytes. By the fourth month of gestation, each ovary contains approximately 10 million primary oocytes and some primordial

follicles (oocytes surrounded by follicular cells). Most of the oocytes degenerate, so that by birth the neonate has approximately 250,000 to 500,000 oocytes; by puberty, only about 200,000 oocytes are left.[15] The oocytes stop developing and will remain in a state of arrested meiosis until puberty. Information regarding ovulation is found later in this chapter in the section discussing the menstrual cycle.

The Bony Pelvis

The bony pelvis has multiple functions. First, it provides an attachment site for the muscles and connective tissue of the pelvis, thereby providing support and stability to the pelvic organs. Second, it provides the site of attachment and articulation for the lower limbs. Third, it supports the weight of the upper trunk and distributes it to the lower extremities. Finally, in the female, the fetus passes through the bony pelvis during childbirth.

Before puberty, males and females possess similar pelvises. Proximate to puberty, however, the female pelvis changes in a manner conducive to pregnancy and birth. When a woman reaches approximately 40 years, the pelvis gradually changes so that it becomes more similar to the pelvis of her male counterpart.[16]

Pelvic Bones

The pelvis comprises four bones: two innominate bones, the sacrum, and the coccyx (**Figure 10-7**).

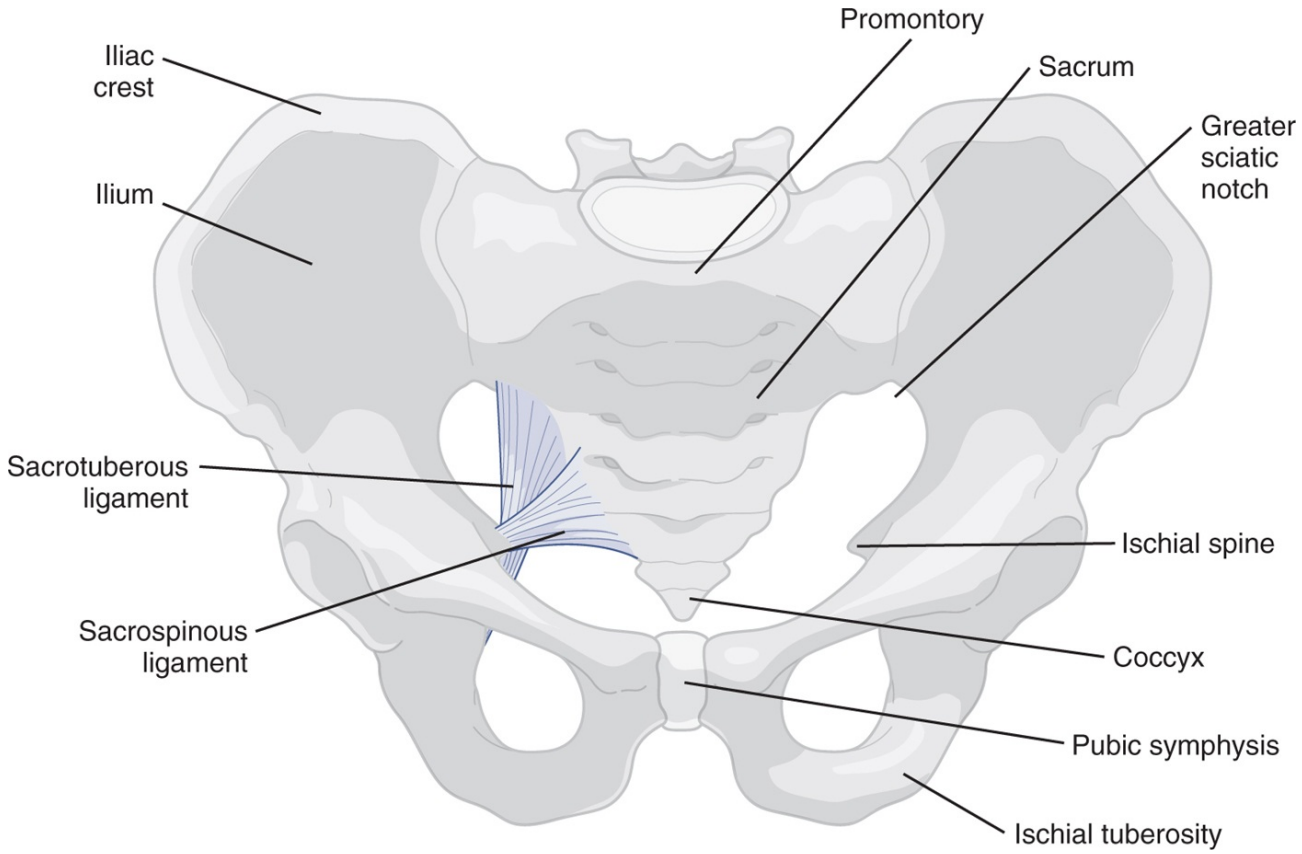

Figure 10-7 Front view of the bony pelvis with ligaments.

Each innominate bone has three parts: the ilium, the ischium, and the pubis. The ilium is the posterior and upper portion of the innominate bone; the two ilia join the sacrum along the sides at the sacroiliac synchondroses. The ischium is the medial and lower portion of the innominate bone. Important bony landmarks of the ischium include the ischial spine, the ischial tuberosity, and the pelvic sidewall. The pubis is the anterior portion of the innominate bone. The two

pubic bones join at the symphysis pubis, where they are attached to an avascular fibrocartilage disc. The inferior margin of the symphysis pubis and the descending rami create the pubic arch, another important bony landmark of the pelvis.

The longitudinal axis of the symphysis pubis is normally parallel to the longitudinal axis of the sacrum. If the symphysis pubis is not at least approximately parallel to the sacrum, the anteroposterior diameters of two of the three pelvic planes that the fetus passes through during birth—namely, the pelvic inlet and the pelvic outlet—can be changed significantly. Tilting of the superior margin of the symphysis pubis toward the sacral promontory and of the inferior margin away from the sacrum is called anterior inclination. Tilting of the inferior margin of the symphysis pubis toward the sacrum and the superior margin away from the sacral promontory is called posterior inclination (**Figure 10-8**).

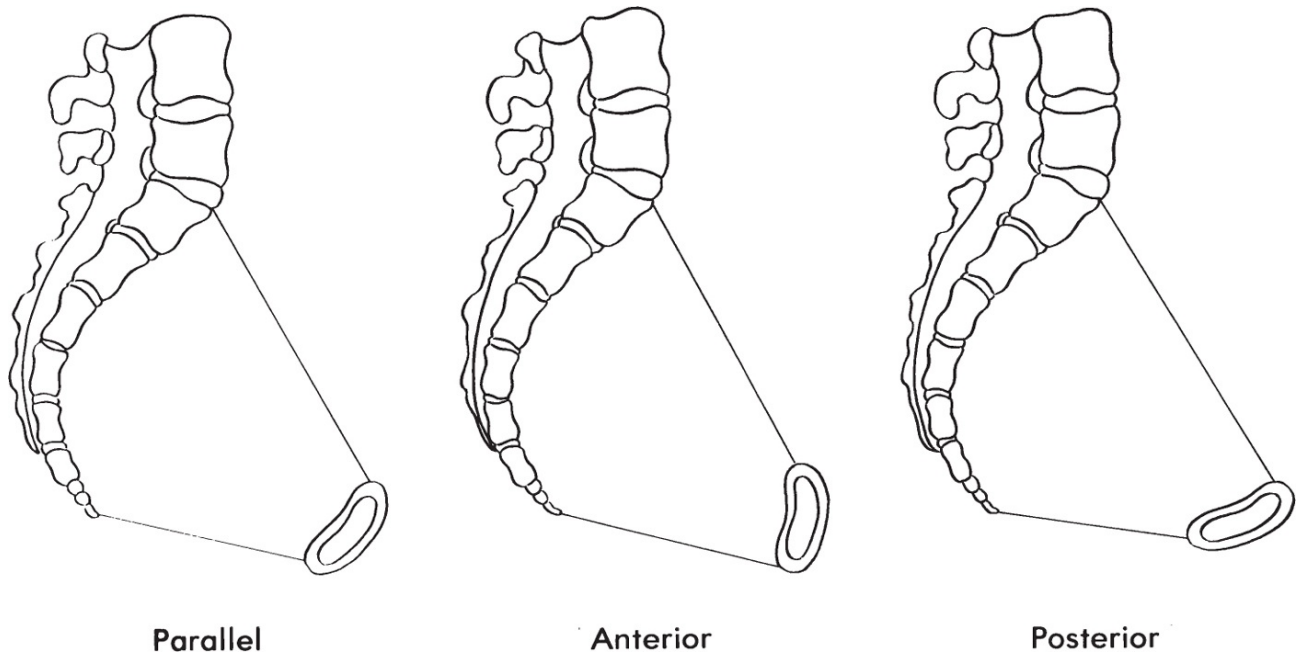

Figure 10-8 Inclination of symphysis pubis.

The sacrum and the coccyx make up the posterior portion of the pelvis. The sacrum is formed by the fusion of the five sacral vertebrae. The superior part of the sacrum, the sacral promontory, is an important bony landmark of the pelvis. The coccyx is formed by the fusion of usually four, or occasionally three or five, rudimentary vertebrae and is itself an important bony landmark. The sacrum and the coccyx join at the sacrococcygeal symphysis.

Pelvic Joints

There are four joints within the bony pelvis: the symphysis pubis, the two sacroiliac synchondroses (or sacroiliac articulations), and the sacrococcygeal symphysis. These joints are made of a network of cartilage and/or ligaments that join the bones of the pelvis. During pregnancy, the joints of the pelvis soften under the influence of the hormones of pregnancy, including relaxin. This softening allows for movement and widening of the pelvis, which increases its potential size to facilitate birth.

The pubic symphysis is composed of fibrocartilaginous tissue. During pregnancy, it widens slightly. Although this widening usually does not exceed 10 millimeters, it may cause tenderness, particularly with motion.[16,17] Rarely, the symphysis pubis may separate spontaneously (or surgically) during labor.

The sacroiliac joints are primarily weight-bearing joints that take the weight of the upper body and distribute it to the lower limbs. They are synovial joints, meaning that the surfaces of the articulating bones are covered by a thin membrane of cartilage and are separated by a joint cavity lined by a synovial membrane that produces a lubricating fluid. The resulting hinge-type movement gives the sacrum the ability to rotate slightly, enlarging the measurements of two of the three pelvic planes that the fetus passes through during birth.

The sacrococcygeal joint is also a synovial hinge joint that allows flexion and extension of the coccyx. Extension occurs during relaxation of the levator ani and rectal sphincter muscles —an event that occurs normally during defecation and during the birth process. Extension of the coccyx increases the anteroposterior diameter of the plane at the pelvic outlet.

Pelvic Ligaments

The term “ligament” is generally used to describe connective tissue that joins two bones. However, in the pelvis, in addition to indicating a connection between bones, the term “ligament” is used to describe a variety of tissues that connect pelvic organs to bones. Nevertheless, the sacrospinous and sacrotuberous ligaments of the sacrum are “true” ligaments in the bony pelvis that help provide stability to the pelvis in part by supporting the sacrum and restricting its ability to tilt.

The sacrospinous ligaments are triangular, with a broad base that attaches to the lateral margins of the sacrum and coccyx and the insertion at the apex of the ischial spine. The coccygeus muscle lies along the pelvic aspect of this ligament. The pudendal nerve, which innervates the skin and muscles of the perineum, lies just posterior to the sacrospinous ligaments where it attaches to the ischial spine. The sacrotuberous ligaments attach to the sacrum at the level of the S3 through S5 vertebrae and extend to the inferior spine of the ilium, where it becomes the ischial tuberosity extending inferior and lateral to the sacrospinous ligaments.

The Pelvic Floor

The pelvic floor is made up of major muscle groups as well as ligaments and fascia that together support the abdominal and pelvic organs, maintain continence, control urination and elimination, and facilitate passage of the fetus during birth. From the most superior to the most inferior, the major components of the pelvic floor are (1) the endopelvic fascia, (2) the pelvic diaphragm, (3) the urogenital diaphragm, and (4) the superficial perineal muscles. The muscles of the pelvic floor are described in **Table 10-1**.

Table 10-1	**Muscles of the Perineum**

Muscle	Description	Function
Pubococcygeus	Primary portion of the levator ani. It originates at posterior border of the symphysis pubis and sweeps back to insert on lateral margins of the coccyx. It is divided into three bands.	
	Pubovaginalis: origin is the posterior aspect of the pubis and insertion is the fascia of the vagina and perineal body. The muscle is in a U shape around the vagina.	Acts as a sling for the vagina and vaginal sphincter (muscle that causes spasm during vaginismus).
	Puborectalis: intermediate fibers that form a U loop around the anal rectal junction and insert into the posterior wall of the rectum, blending with the anal sphincter.	Sling and accessory sphincter for the rectum.
	Pubococcygeus proper: lateral fibers that go directly back to form a Y and insert on the lateral margins of the coccyx.	Flexes the coccyx to increase anal–rectal flexure and control defecation.
Iliococcygeus	Arises from a facial line on the obturator internus muscle along the pelvic wall of the obturator foramen and extends to insert on the lateral margins of the coccyx and anococcygeal raphe.	Pelvic organ support and urinary continence.
Bulbocavernosus	Two bulbocavernosus muscles. Posteriorly, they attach to the central tendinous point of the perineum; anteriorly, they insert into the corpus cavernosus of the clitoris; laterally, they surround the orifice of the vagina, covering the vestibular bulbs and Bartholin glands on either side.	Known as the sphincter vaginae, contraction of these muscles reduces the size of the vaginal orifice. Contraction of the anterior muscle fibers contributes to clitoral erection.
Ischiocavernosus	Two ischiocavernosus muscles, one on either lateral boundary of the perineum. Posteriorly, they arise from the inner surface of the ischial tuberosities; anteriorly, they cover and insert into the sides and posterior surface of the crus clitoris; laterally, they extend from the clitoris to the ischial tuberosities along the ischial ramus, from which they derive some of their fibers.	Maintain clitoral erection.
Superficial transverse perineal (transversus perinei superficialis)	Two superficial transverse perineal muscles arise from the inner and anterior surfaces of the ischial tuberosity of the superior ramus of the ischium by a small tendon; they insert into the central tendinous point of the perineum.	Fix the location of the central tendinous point of the perineum.
Perineal membrane	Arises from the inferior ramus of the ischium, spans the anterior pelvic outlet, and is attached to the lateral vaginal walls. The urethra passes through this membrane.	Helps to stabilize the vagina.
Central tendinous point of the perineum	A fibromuscular structure in the midline between the vagina and the anus, and at the base of the urogenital diaphragm. The tissue is fibrous because it is the point of fusion for both the superior and inferior fascia of the urogenital diaphragm and the external perineal and Colles' fascia; it has muscular fibers because it is a common point of attachment for a number of muscles whose fibers blend together into the central tendinous point of the perineum, among them the bulbocavernosus, superficial transverse perineal, some fibers of the deep transverse perineal, external anal sphincter, and the levator ani–pubococcygeus.	Common point of attachment for a number of layers of fascia and muscles.

The endopelvic fascia is a layer of connective tissue that surrounds the vagina and provides support to it and to the visceral organs. This fascia also plays a role in urinary continence by providing support to the urethra and neck of the bladder.[18,19]

The pelvic diaphragm separates the pelvic cavity from the perineal space and can be envisioned as a diamond-shaped hammock that supports the viscera, abdominal organs, and pelvic organs. The pelvic diaphragm consists of the levator ani muscles, composed of the puborectalis, pubococcygeus, and iliococcygeus; the coccygeus muscle; and their associated fascia (**Figure 10-9**). Insertions of the muscles of the levator ani group around the vagina, urethra, and rectum allow passage of these openings and create functional sphincters that contribute to fecal and urinary continence. The levator ani maintains the position of the pelvic organs. This muscle originates at the posterior surface of the superior ramus of the pubis, then runs along the arcus tendineus, a line of fascia on the internal surface of the ischium. The levator ani inserts into the last segments of the coccyx laterally and into tendons on the rectum, vagina, and urethra medially, so that they make up part of the sphincters for these organs.

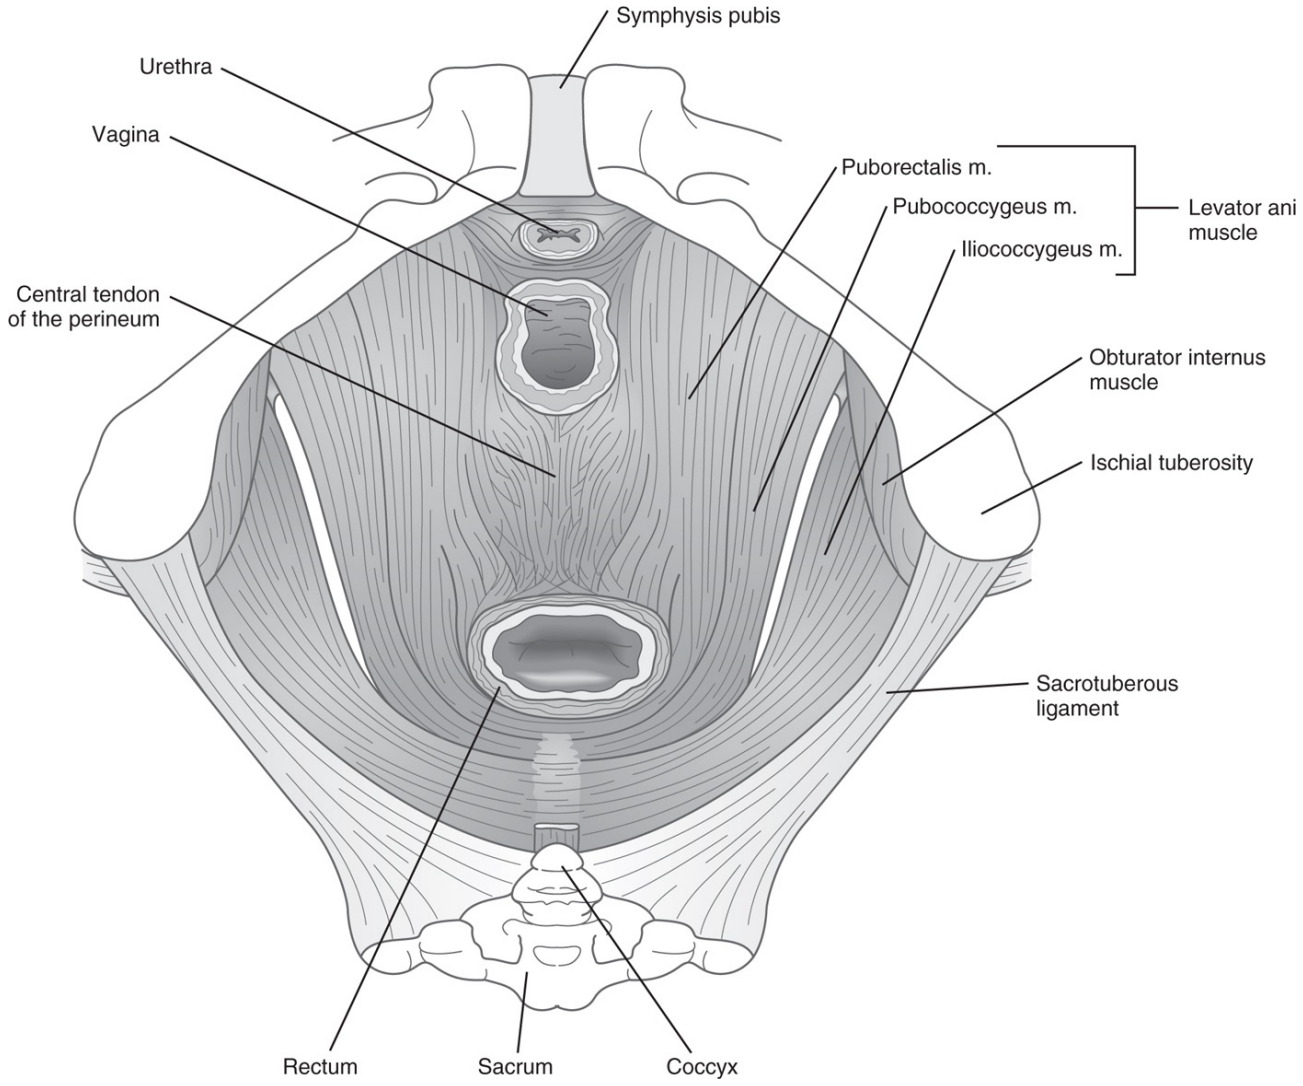

Figure 10-9 Superior view of the structures of the pelvic diaphragm.

When the muscles of the pelvic floor become damaged, which can occur during childbirth, support of the urethra and other pelvic structures becomes increasingly dependent on the ligaments and fascia. Under the strain of continuous or prolonged stretching, these ligaments and fascia can fail and become unable to prevent organ prolapse and/or stress incontinence.

Perineal Membrane

The perineal membrane is a fibrous sheet that spans the urogenital triangle just inferior to the pelvic diaphragm. The urogenital triangle is an equilateral triangle defined by the pubic symphysis and ischial tuberosities. The perineal membrane has historically been called the urogenital diaphragm. However, newer studies suggest that the urogenital diaphragm is really a single layer of muscle and fascial tissue that should be referred to as the perineal membrane.[20] The urethra and the vagina pass through this membrane.

Superficial to the perineal membrane are the bulbocavernosus, ischiocavernosus, and superficial transverse perineal muscles (**Figure 10-10**). The perineal body and central tendinous point of the perineum, which crosses the midline of the perineum between the vaginal and anal openings, is the point of convergence of the superficial transverse perineal muscle, the urogenital sphincter, the bulbocavernosus muscles, and the external anal sphincter. This perineal body is also the point of attachment of the two sides of the perineal membrane, provides support to the posterior vaginal wall, and helps prevent rectal prolapse. Damage to the perineal body, in addition to stretching of the levator ani muscles that may occur during the second stage of labor, can result in rectal prolapse.

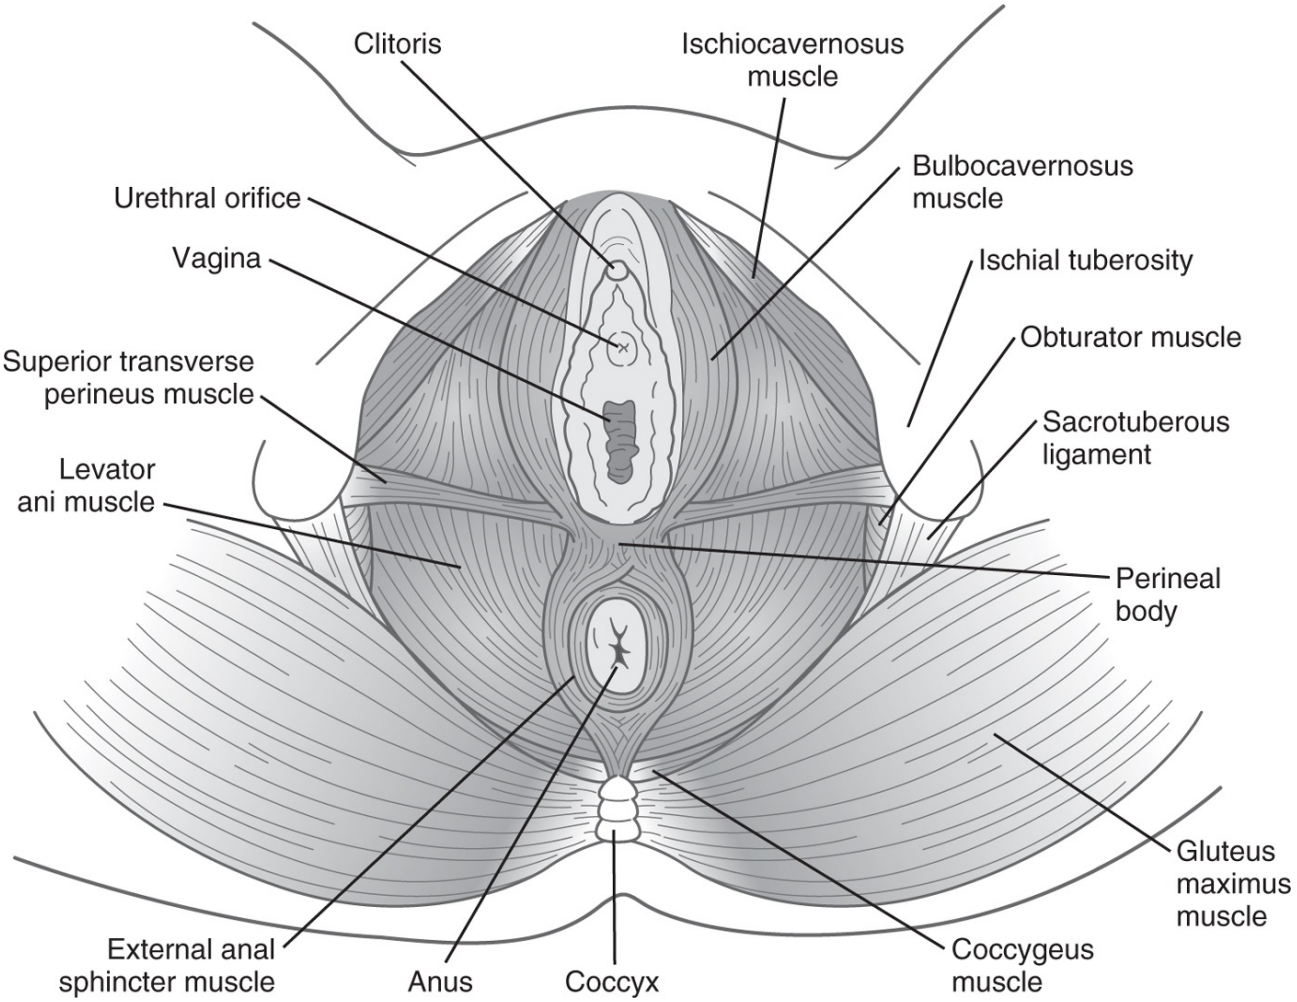

Figure 10-10 Inferior superficial view of the structures of the perineum.

An understanding of how pelvic floor anatomy promotes urinary and fecal continence is necessary to understand how changes related to pregnancy, childbirth, and aging result in some women developing pelvic floor dysfunction, including stress urinary incontinence.

Bladder and Urethra

In a female, the urethra is approximately 4 centimeters long and runs posteriorly along the pubic symphysis from the external opening (urethral meatus) to the bladder. The urethra is composed of an inner layer of epithelium surrounded by a layer of vascular tissue and a layer of muscular tissue, which together help maintain the urethra in a constricted position. The urethra is stabilized by the pubourethral ligaments, which attach the anterior portion of the urethra to the symphysis pubis. To maintain urinary continence, urethral constricting pressure must be greater than bladder pressure. This pressure balance is achieved in part by the constriction provided by the urethral muscles and sphincters and in part by the support/compression provided by the pelvic floor muscles and their associated structures.

Two sphincter structures are involved in urinary continence: the inner sphincter at the neck of the bladder and the external urethral rhabdosphincter/urethrovaginal sphincter complex. The inner sphincter is an extension of the detrusor smooth muscle of the bladder that is under

autonomic control, whereas the urethral rhabdosphincter/urethrovaginal sphincter complex is composed of skeletal muscle and is under voluntary control. Support by the pelvic floor musculature is also critical to maintaining urinary continence. The major components of this supportive structure are the vaginal wall, the endopelvic fascia, the arcus tendineus fasciae pelvis, and the levator ani muscles. The endopelvic fascia surrounds the vagina and attaches to the arcus tendineus fascia, which serves to suspend and support the urethra.

The urethra exits the pelvis via the urogenital hiatus of the levator ani, through which the vagina also passes. The baseline muscle tone of the levator ani, therefore, is critical in maintaining urinary continence by keeping the urethra compressed.

Anorectal Anatomy

The anal canal is approximately 2.5 to 5 centimeters in length. The anal sphincter surrounds the anal canal and is a multilayer structure that includes the anal mucosal lining, the internal sphincter, and the external sphincter. The internal anal sphincter comprises a layer of muscle that is a continuation of the muscular layer of the rectum, ending approximately 1 centimeter from the anal opening.[21] Similar to the internal sphincter, the external anal sphincter is a cylindrical muscular structure; it is partially interwoven with the levator ani muscle and extends all the way to the anal opening. The external anal sphincter is composed of striated muscle under voluntary control.

Pelvic Nerves and Vasculature

The perineum is perfused by the internal pudendal artery and branches of the pudendal artery, including the inferior rectal artery. These vessels are branches of the anterior division of the internal iliac (hypogastric) artery. Perineal innervation occurs via the pudendal nerve and its branches, which originate from S2, S3, and S4. The pudendal nerve also innervates the levator ani, rectal sphincter, skin of the vulva and lower portion of the birth canal, and muscles of the urogenital diaphragm.

The Obstetric Pelvis

The pelvis is divided into the “false pelvis” and the “true pelvis” by the linea terminalis, an invisible line that runs along the pelvic brim from the superior part of the symphysis pubis around to the sacral promontory (**Figure 10-11**). The false pelvis, which includes the iliac fossa and iliac crest, is deemed “false” because it has little obstetric significance yet defines the lower border of the abdominal cavity. The true pelvis constitutes the bony passageway through which the fetus must maneuver to be born vaginally. This bony passage is actually a curved canal with a shallow anterior wall that is approximately 5 centimeters long, and a deep concave posterior wall that is approximately 10 centimeters long.

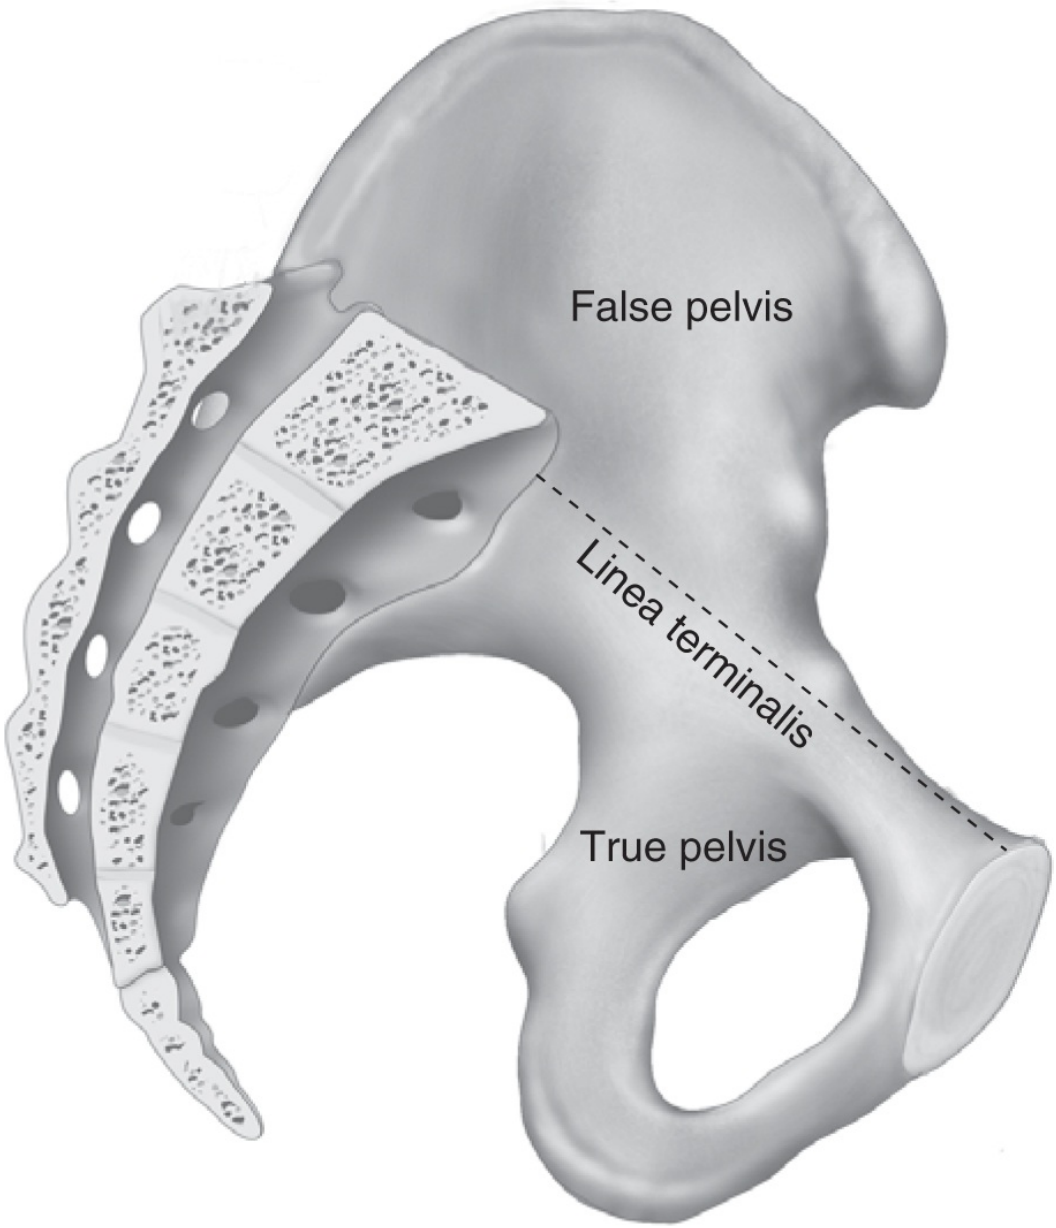

Figure 10-11 The linea terminalis is a plane that separates the true and false pelvis. The linea terminalis is made of the superior posterior border of the symphysis pubis, iliopectineal (acruate) line, and sacral promontory.

The true pelvis has five boundaries:

1. *Superiorly:* the sacral promontory, linea terminalis, and upper margins of the pubic bones
2. *Inferiorly:* the inferior margins of the ischial tuberosities and the tip of the coccyx
3. *Posteriorly:* the anterior surfaces of the sacrum and the coccyx
4. *Laterally:* the sacroiliac notches and ligaments and the inner surfaces of the ischial bones
5. *Anteriorly:* the obturator foramina and the posterior surfaces of the symphysis pubis, pubic bones, and ascending rami of the ischial bones

Clinically Important Aspects of the True Pelvis

The birth canal shape is determined by the architecture of the sacrum, sacrosciatic notch, sidewalls, ischial spines, and subpubic arch. Therefore, the shape of the true pelvis has several clinically relevant aspects.

The true pelvis has three planes of obstetric significance: the inlet, the midplane, and the outlet (**Table 10-2**). Each of these planes has anteroposterior and transverse diameters of import that are critical for evaluation of pelvic adequacy for vaginal birth.

Table 10-2 **Pelvic Planes and Obstetric Diameters**

Plane	Boundaries of Plane	Significant Obstetric Diameters of Plane
Pelvic inlet: (superior strait): upper entry into the true pelvis	**Posterior:** sacral promontory **Lateral:** iliopectineal (arcuate) line that extends to the horizontal rami superior posterior edge of the pubic bones **Anterior:** superior posterior border of the symphysis of the symphysis pubis	**Anteroposterior diameters:** 1. *Conjugata vera:* true conjugate of the inlet; extends from the middle of the sacral promontory to the middle of the upper posterior margin of the symphysis pubis; this diameter is normally 11 cm or more. 2. *Obstetric conjugate of the inlet:* extends from the middle of the sacral promontory to the middle of the posterior symphysis pubis. The pelvis is considered contracted if the obstetric conjugate measures less than 10 cm. 3. *Diagonal conjugate of the inlet:* extends from the middle of the sacral promontory to the middle of the inferior (lower) margin of the symphysis pubis. This is the only diameter of the pelvic inlet that can be measured clinically. A normal clinical measurement is considered to be 11.5 cm or more. **Transverse diameter:** greatest distance between the linea terminalis on either side of the pelvis; this distance is approximately 13.5 cm. **Oblique diameters:** distance between the sacroiliac synchondrosis on one side of the pelvis and the iliopectineal eminence on the opposite side of the pelvis. The oblique diameters average slightly less than 13 cm (12.75 cm) each.
Pelvic midplane: plane of least dimensions	**Posterior:** sacrum at the junction of the fourth and fifth sacral vertebrae **Lateral:** ischial	**Transverse diameter (interspinous diameter):** distance between the ischial spines. Normally measures approximately 10 cm. Smallest diameter of the pelvis that the fetal presenting part must accommodate during the process of labor and birth. **Anteroposterior diameter:** extends from the middle of the inferior

	spines **Anterior:** inferior border of pubic symphysis	margin of the symphysis pubis through the middle of the transverse diameter and to the sacrum. This diameter is normally 11.5 cm or more.
Pelvic outlet: can be thought of as composed of two triangles, with the transverse diameter of the outlet serving as the common base of these two triangles	**Posterior:** sacrococcygeal joint **Lateral:** inner surface of ischial tuberosities **Anterior:** lower border of pubic symphysis	**Anteroposterior diameter:** extends from the middle of the inferior margin of the symphysis pubis to the sacrococcygeal joint. This measurement is normally 11.5 cm or more. **Transverse diameter (intertuberous, or biischial, diameter):** distance between the inner aspect of the lowermost part of ischial tuberosities. This diameter has a measurement of approximately 10 cm.

The descending rami of the pubic bones and the inferior margin of the symphysis pubis form what is known as the pubic arch. The angle of this arch should be at least 90°, as determined just below the symphysis pubis. An arch that is 90° a few centimeters below the symphysis pubis but narrow above that (just below the symphysis pubis) decreases the available space in the anteroposterior diameter of the pelvic outlet.

The inner aspect of the forepelvis (the anterior portion of the pelvis) should be rounded. A forepelvis that is not rounded but instead angles sharply toward the lateral portion of the pelvis decreases the oblique diameters of the inlet.

The pelvic sidewalls extend from the upper anterior angle of the sacrosciatic notch at the point of the widest transverse diameter of the pelvic inlet in a downward and forward line to the ischial tuberosities at the point of the widest transverse diameter of the pelvic outlet. They are normally slightly convergent in that, if the lines of their angles were extended beyond the pelvis, the two lines would meet at about the level of the knees; however, when palpated, they feel generally straight. The obstetric importance of the pelvic sidewalls hinges on the angle of the sidewalls. Divergence or convergence is based on whether the point of origin of the sidewall at the inlet and the ending point of the sidewall at the ischial tuberosities are essentially equidistant from the anteroposterior diameter of the pelvis. Convergent sidewalls usually decrease the angle of the pubic arch and may be accompanied by more prominent ischial spines. Divergent sidewalls always indicate a very wide angle of the pubic arch.

The shape and width of the sacrosciatic notch are important because they affect the posterior sagittal diameter of the inlet. This factor combines with the shape and rotation of the sacrum to determine the amount of room in the posterior portion of the pelvis for passage of the fetus.

Pelvic Types

Each plane of the pelvis has a shape, defined by the anterior–posterior and transverse diameters. These shapes were classified into four basic pelvic types by Caldwell and Moloy in X-ray studies done in the 1920s:[22] (1) gynecoid, (2) android, (3) anthropoid, and (4) platypelloid (**Table 10-3**). The pelvic types are determined by the shape of the pelvic inlet and the posterior characteristics of the pelvis, including the posterior sagittal diameter, which is the distance from the midpoint of the transverse diameter to the sacral promontory. Anatomic portions of the pelvis used in evaluation of pelvic types are the inlet, sacrum, sacrosciatic

notch, sidewalls, ischial spines, and pubic arch. Characteristics of these structures influence the obstetric capacity of the pelvis.

Table 10-3	Pelvic Types and Their Identifying Characteristics	
Pelvic Type and Description	**Identifying Characteristics**	**Image**
Gynecoid		
Commonly known as the “female pelvis” because it is the type that occurs most frequently in women; 41–42% of women’s pelves are gynecoid. This shape is optimal for childbearing.	*Inlet:* rounded. Transverse diameter approximately greater than or equal to the anteroposterior diameter. Posterior sagittal diameter only a little shorter than the anterior sagittal diameter. *Sacrum:* parallel with the symphysis pubis. *Sacrosciatic notch:* rounded with an approximate distance of 2½ to 3 fingerbreadths along the sacrospinous ligament. *Sidewalls:* straight pelvic sidewalls. *Ischial spines:* blunt and neither prominent nor encroaching. *Pubic arch:* a wide arch (≥ 90 degrees).	
Android		
Commonly known as the “male pelvis” because it occurs more frequently in men. Occurs in 32.5% of white women and in 15.7% of nonwhite women. The android pelvis poses difficulty for vaginal birth and increases the incidence of posterior position and forceps-assisted delivery. The midplane and outlet contracture of the android pelvis increases the incidence of fetopelvic disproportion and cesarean section.	*Inlet:* heart shaped. Posterior segment is wedge shaped; anterior segment (forepelvis) is narrow and triangular. The posterior sagittal diameter is short in comparison to the anterior sagittal diameter. Limited space in the posterior portion of the pelvis for accommodating the fetal head. *Sacrum:* anteriorly inclined and flat. *Sacrosciatic notch:* highly arched and narrow, with an approximate distance of 1½ to 2 fingerbreadths along the sacrospinous ligament. *Sidewalls:* pelvic sidewalls usually convergent. *Ischial spines:* prominent and frequently encroaching, thereby decreasing the transverse (interspinous) diameter of the midplane. *Pubic arch:* narrow, with an acute angle of much less than 90 degrees.	
Anthropoid		
The anthropoid pelvis is most common among women who are nonwhite, occurring in 40.5% of nonwhite women as compared to	*Inlet:* oval. The anteroposterior diameter is much larger than the	

23.5% of white women. The anthropoid pelvis had the longest sacrum of the four types of pelves and, therefore, is the pelvis with the most generous posterior portion. The potential problem of outlet contracture because of a narrow pubic arch is counterbalanced by the lengthy anteroposterior diameter, thus providing room in the posterior portion of the pelvis for the fetus. The shape of the anthropoid pelvis favors a posterior position of the fetus. It is adequate for vaginal birth if the dimensions overall are relatively large.	transverse diameter. The anterior segment of the pelvis (forepelvis) is pointed and narrower than the posterior segment. *Sacrum:* posteriorly inclined, so the posterior sagittal diameters are long throughout the pelvis. This allows more space in the posterior portion of the pelvis for accommodating the fetal head. *Sacrosciatic notch:* of average height but quite wide; has an approximate distance of 4 fingerbreadths along the sacrospinous ligament between the ischial spine and the sacrum. *Sidewalls:* somewhat convergent. *Ischial spines:* usually prominent but not encroaching. Transverse (interspinous) diameter of the midplane is generally less than that of the gynecoid pelvis but not as contracted as the android pelvis. *Pubic arch:* somewhat narrow.	
Platypelloid		
Platypelloid pelvis is rare and not particularly conducive to vaginal birth. It is the widest of all pelvic types and also shallow. These characteristics make rotation and descent of the fetal head difficult. This shape occurs in less than 3% of women in both white and nonwhite races.	*Inlet:* flat. Short anteroposterior diameter and a wide transverse diameter. The anterior segment of the pelvis (forepelvis) is quite wide. *Sacrum:* inclined posteriorly and quite hollow. *Sacrosciatic notch:* wide and flat, with an acute angle between the ischial spines and the sacrum. *Sidewalls:* slightly convergent. *Ischial spines:* somewhat prominent but, because of wide transverse diameters throughout the pelvis, this prominence has no effect. *Pubic arch:* quite wide. This pelvis is the widest of all the pelvic types.	

Caldwell and Moloy went on to characterize the labor outcomes associated with each type of pelvis. They generated essential knowledge of the mechanisms of labor as well as information about how the position and diameter of the fetal head affects the progress of labor.[22] This information is a critical component of the assessment of fetal descent during labor.

The pelves of most women are not pure types, but rather a mixture of types. By convention, the pelvis is named for the posterior characteristics with a *tendency* for the anterior characteristics. For example, a pelvis with a curved sacrum and wide sacrosciatic notch may have slightly convergent sidewalls that narrow the anterior segment of the midpelvis and

outlet. Such a pelvis would be described as a gynecoid pelvis with android tendencies.

The Menstrual Cycle: An Introduction

"Menstruation" is a term derived from the Latin word *mensis*, meaning "month." In several cultures, if not most, this single biological event engenders negative connotations. According to the *British Medical Journal* in 1878, "it is undoubtedly the fact, that meat will be tainted if cured by women at the catamenial [*sic* menstrual] period."[23] In today's English language, euphemisms for the event abound, including "the curse" and "being sick this month." In the Polynesian language, the word "taboo" is synonymous with "menstruation."[24] Even today, national advertisements for sanitary products continue to avoid using the term "menstruation."

Much still remains unknown about the menstrual cycle, including the basic question of the role of menstruation for a healthy woman. Although human females usually menstruate monthly, some other primates do not; many other mammals have an estrus cycle that includes ovulation and reabsorption instead of menstruation. Some scientists, such as the evolutionary biologist Profit, have postulated that menstruation is useful to a woman because it expels bacteria from the body.[25] Others question whether menstruation has any benefits and instead should be considered obsolete. These scientists are among those who advocate that the average woman who wants contraception should use regular hormonal suppression.[26]

The physiology of the menstrual cycle is a sophisticated process. Over the last few decades, scientific discoveries have revealed more information about the interplay between functions of the female organs and the hormonal milieu. As additional discoveries have been made, understanding the process has become more complicated.

As part of understanding the menstrual cycle, a few assumptions are made. Predominant among them is that every woman has a 28-day cycle and is ovulatory. Neither of these "facts" is necessarily true. The normal menstrual cycle can be 24 to 35 days in duration and can be more variable in the first 5 to 7 years after menarche and in the last 10 years before menopause.

The menstrual cycle has two phases: The follicular phase starts with the onset of menses and ends on the day before the luteinizing hormone surge occurs. The luteal phase begins on the day of the luteinizing hormone surge and ends at the onset of menses. For the purpose of explanation, the menstrual cycle events are initially separated and presented in a set time sequence. Nevertheless, it must be recognized this type of presentation is an artificial convention. The discussion of the menstrual cycle presented in this chapter divides the physiology into several sections, beginning with a discussion of the steroidogenesis and hypothalamic–pituitary–ovarian axis. Next the anatomy of the ovarian cycle with associated physiology and anatomic developments is reviewed, and finally the endometrial cycle is presented.

Steroidogenesis

A number of hormones exist in the human body, which generally are one of three different types: amines, prostaglandins, or steroid hormones. Sex hormones, also termed gonadocorticoids, are steroid hormones. All sex steroid hormones are synthesized from cholesterol through a series of chemical reactions known as steroidogenesis. Sex steroids are commonly identified as estrogen, progesterone, and androgen. The major site of biosynthesis for all sex steroid hormones in healthy ovulating women is the ovary. Other peripheral sites, including adiposity and skeletal muscle, produce small amounts of these hormones.

All of the sex hormones are derived from the 27-carbon-chain cholesterol. From the 27 carbons, a mitochondrial enzyme called P450 scc ("scc" signifies cholesterol side-chain cleavage) catalyzes conversion of cholesterol to pregnenolone. Pregnenolone is the precursor from which 21-carbon-chain progestogens and corticoids emerge. Further chemical reactions reduce the carbons from hydroxypregnenolone to 19-carbon-chain androstenedione, the precursor from which androgens, including testosterone, are derived. Aromatization further reduces the 19 carbons to the 18-carbon-chain estranes, which include all of the estrogens[27,28] (**Figure 10-12**). In summary, steroidogenesis is an exquisitely efficient method by which all sex hormones are derived in a few chemical steps by starting with cholesterol and reducing the carbons in cholesterol from 27 to 18 in number.

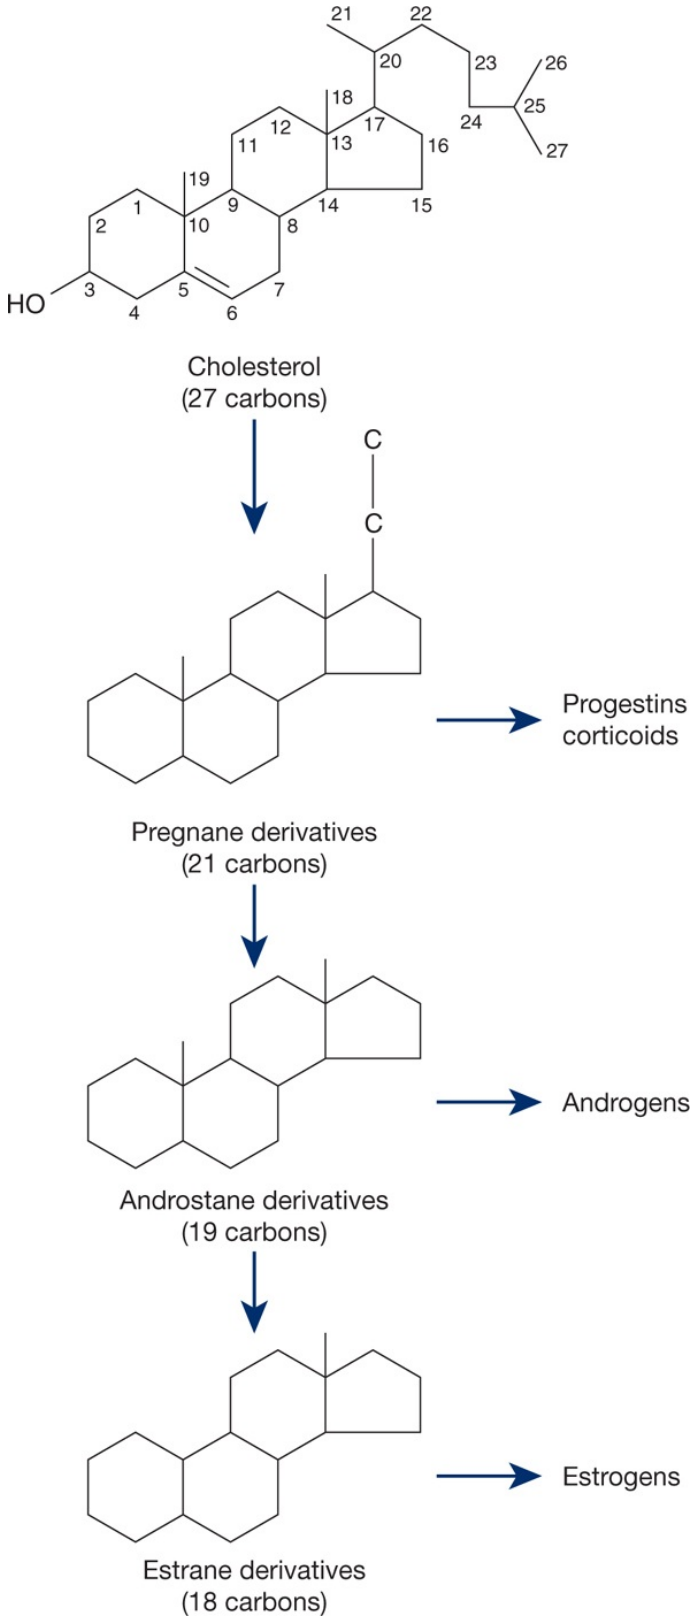

Figure 10-12 Biosynthesis of sex steroids.

Steroidogenesis does not occur without interaction with the gonadotropins, follicle-

stimulating hormone (FSH), luteinizing hormone (LH), and normal reproductive organs. Production of FSH and LH is part of the hypothalamic–pituitary–ovarian axis, as illustrated in **Figure 10-13**.

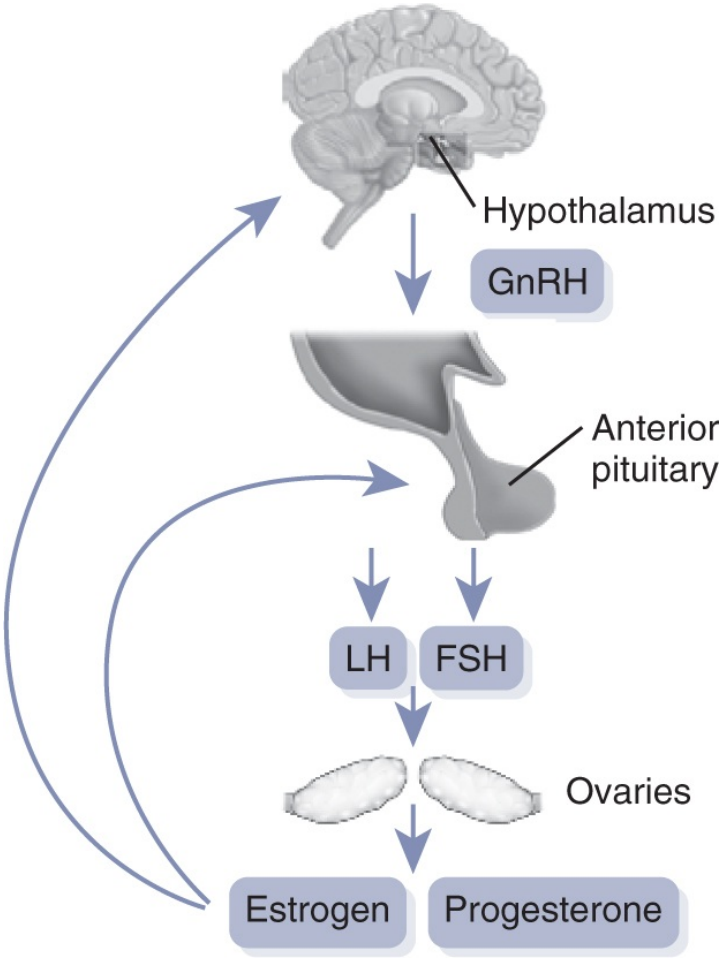

Figure 10-13 The hypothalamic–pituitary–ovarian axis.

Abbreviations: FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

The Hypothalamic–Pituitary–Ovarian Axis

"Hypothalamic–pituitary–ovarian axis" is the term used when referring to the effects created by these individual endocrine organs when they work in concert as if they were a single endocrine organ. As will be described, the interplay between the hypothalamus, pituitary, and ovary is controlled through feedback loops.

The hypothalamus controls the reproductive system by secreting, in a pulsatile fashion, either releasing or inhibitory factors into the hypothalamic–pituitary portal system.[29] These factors then act on the anterior pituitary gland. The hypothalamus releasing factors that control reproduction include follicle-stimulating releasing factor (FRF), luteinizing hormone releasing factor (LRF), and prolactin-inhibiting factor (PIF). The releasing factors FRF and LRF also are collectively referred to as gonadotropin-releasing factors.

The pituitary gland is composed of two main lobes: the adenohypophysis and the neurohypophysis. When stimulated by hypothalamic releasing hormones, the cells of the adenohypophysis secrete the gonadotropins FSH and LH as well as prolactin. After their release, LH and FSH travel via the circulation to the ovary. A woman's ovaries are the site of production of estrogen and progesterone from either the ovarian theca or granulosa cells.

Control of the Hypothalamic–Pituitary–Ovarian Axis Through Feedback Loops

A feedback system is a method in which factors either inhibit or stimulate production of a specific agent. Positive feedback indicates stimulation, whereas negative feedback is inhibitory. It was not long ago that the feedback system for the hypothalamic–pituitary–ovarian axis was depicted as a simple graph, which was then used as the universal prototype to illustrate negative feedback in basic science classes. However, this simple diagram failed to account for several factors found in a woman's body. For example, gonadotropin-releasing hormone (GnRH) is not static but rather pulsatile, with its release amplitude changing as the result of feedback modulation of steroids and peptides that originate in the dominant follicle and act directly on the hypothalamus and anterior pituitary.

Also, although the hypothalamic–pituitary–ovarian axis sometimes does function as a negative feedback system, it does not exclusively fill this function, nor are estrogen and progesterone the only agents of note that are involved in the hypothalamic–pituitary–ovarian axis. Some agents stimulate the hypothalamus *and* the pituitary, others stimulate neither, and still others stimulate one but not the other. For example, *low* levels of estrogen *inhibit* LH, whereas *high* levels of the same hormone *stimulate* LH.

Among the factors that influence feedback are three specific peptides—inhibin, activin, and follistatin—that are synthesized by ovarian granulosa cells in response to FSH stimulation and secreted into the follicular fluid. Inhibin has two different subtypes: Inhibin A and Inhibin B. As the name implies, both inhibit FSH secretion. This peptide also augments LH stimulation of theca cells to accelerate production of androgens, and it diminishes actions of GnRH. In contrast, activin simulates FSH and diminishes progesterone production from the granulosa cells. It is hypothesized that follistatin, the third major peptide, may inactivate activin by binding it, thereby decreasing FSH activity.

Other factors are also known to have important actions on ovarian function. For example, the ovary is a site of production for insulin-like growth factor 1 (IGF-1), which acts independently of most other factors. This growth factor also amplifies androgen production in ovarian theca cells and FSH action in granulosa cells. In general, FSH has multiple activities in the granulosa cells, with all being influenced by growth factors—of which IGF-II is theorized to be the most important.[30]

In summary, no simple feedback loop exists that describes the entire menstrual cycle. The menstrual cycle is known to have a potent negative feedback system. Importantly, at different times of the cycle, a positive feedback process may be seen as well. In general, as more factors influencing the hypothalamic–pituitary–ovarian axis feedback loop are discovered, there is greater acknowledgment that much remains unknown.

The Ovarian Cycle

Some midwives like to remind a woman that if she is pregnant with a daughter, she also is carrying the eggs for her grandchildren. The intrauterine daughter, like all women, has the largest number of primary oocytes when she is a fetus of approximately 20 to 28 weeks' gestational age. The number of primary oocytes decreases from millions to thousands by the time of puberty via atresia. The mechanism of atresia itself is not well understood.

After establishment of menses, meiosis occurs monthly as part of ovum maturation. During this process, the primary oocyte, which originally had 46 chromosomes, splits into a secondary oocyte consisting of 23 chromosomes and a polar body. The latter usually disappears and is reabsorbed. Granulosa cells surround each secondary oocyte, and the surrounded oocyte is called a primordial follicle (**Figure 10-14**). Follicles are scattered throughout the cortical zone of the ovary.

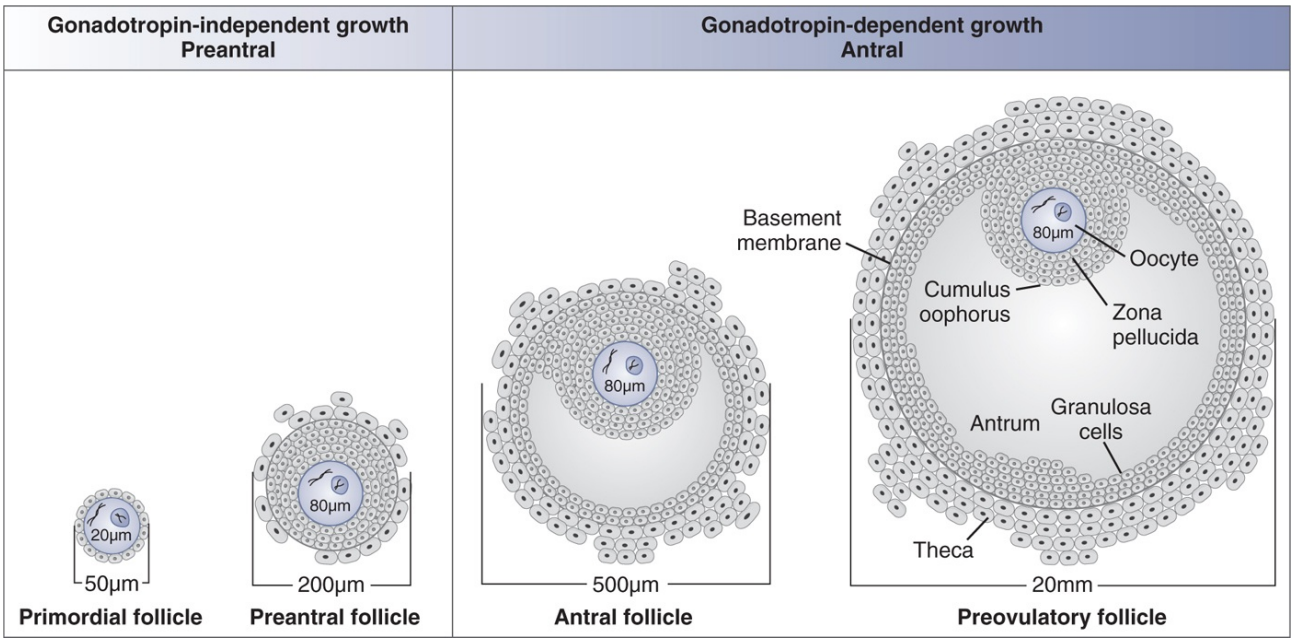

Figure 10-14 Follicular development.

During her reproductive life, a woman's ovaries tend to be in a constant state of change. These changes are characterized by the ovarian cycle within the menstrual cycle. The ovarian cycle is subdivided into two major phases—follicular and luteal phases—with events such as ovulation and menstruation identified separately. Because hormones are receptor specific, the cells within the ovary contain receptor sites that are essential to normal ovarian function and a normal menstrual cycle. As the various ovarian changes occur, receptors on ovarian cells appear and interface with the feedback system.

Follicular Phase of Ovarian Cycle

The follicular phase varies in length but averages 10 to 14 days. This phase of the ovarian cycle produces an ovum for fertilization.

Follicles can be found in an ovary at different stages of maturation. Groups of immature

ovarian follicles develop over time. Taking more than a year on average, these primordial follicles grow until one major follicle matures and the others regress. As early as menstrual cycle day 5, one follicle out of a group begins to emerge as dominant. It remains unknown why one follicle is chosen and others regress to stromal tissue, but local growth factors are theorized to be involved. During the dominant follicle's development, it has an increased number of FSH receptors compared to other follicles, enabling production of its own estrogenic environment. As estrogen levels in the circulation increase secondary to follicular production, a concomitant decrease in FSH secretion occurs—an action that may seal the fate of those follicles unable to produce an estrogenic milieu. Simultaneously, theca cells grow rapidly in the ovary. Perhaps in response to the high estrogen level, the granulosa cells of the dominant follicles begin to develop LH receptors.

Preantral Follicle

As a primordial follicle grows, a layer of theca cells forms around the granulosa cells, with a basement membrane separating the two groups. This follicle then is known as a preantral follicle. Under the influence of FSH, the granulosa cells surrounding the maturing follicle proliferate and begin to produce androgens and estrogens, especially the latter. FSH receptors appear on the preantral granulosa cells. Using energy from cyclic adenosine monophosphate (cAMP), the cell is able to convert, though aromatization, androgens into estrogens as described in the discussion of steroidogenesis. Simultaneously, the theca cells, which have LH receptors, use cAMP to produce the androgens. In the preantral follicle, FSH and estrogen promote the development of more FSH receptors.

Although the follicular cycle usually progresses normally, in some women large amounts of androgens are produced. When this occurs, the granulosa cells cannot compensate for these high levels of androgens and convert the androgen into estrogen. In such a case, eventually the follicle regresses secondarily to atresia. This phenomenon is noted to occur among women with polycystic ovary syndrome, a topic discussed in more detail in the *Gynecologic Disorders* chapter.

Antral Follicle

Eventually a cavity, called the antrum, forms in the intercellular spaces of the granulosa cells. The appearance of the antrum is pathognomonic (i.e., clearly indicative) of the antral follicle. The antrum is filled with fluid that is heavily estrogenic in nature. Like the preantral follicle, the antral follicle continues to have LH receptors exclusively on theca cells and FSH receptors only on the granulosa cells.

Preovulatory Follicle

The outer layer of the follicle becomes somewhat translucent, at which point it is termed the zona pellucida. The zona pellucida then is surrounded by more granulosa cells, also known as the corona radiate. The zona pellucida is attached to the main body of the follicle by a mass of granulosa cells, called the "egg cloud" or cumulus oophorus. When these changes become

apparent, this follicle is called the preovulatory follicle or the Graafian follicle. By day 12 or 13 of a menstrual cycle, the oocyte is floating in the antrum; by cycle day 14, the mature or Graafian follicle is protruding from the ovary. Even before ovulation occurs, the granulosa cells begin to increase in size and assume a yellow shading of lutein as the LH receptors appear on the cells.

As illustrated in **Figure 10-15**, the hormones estrogen and LH are intimately related to each other. Approximately 24 to 36 hours before ovulation, estrogen levels peak, priming the cycle for the LH surge. Some researchers have found that women athletes are more likely to sustain injuries when estrogen is high during this time and theorize this propensity is related to collagen metabolism, a process influenced by estrogen.[31] At this time, androgen levels also begin to increase, perhaps in an evolutionary-based effort to stimulate the libido.[32]

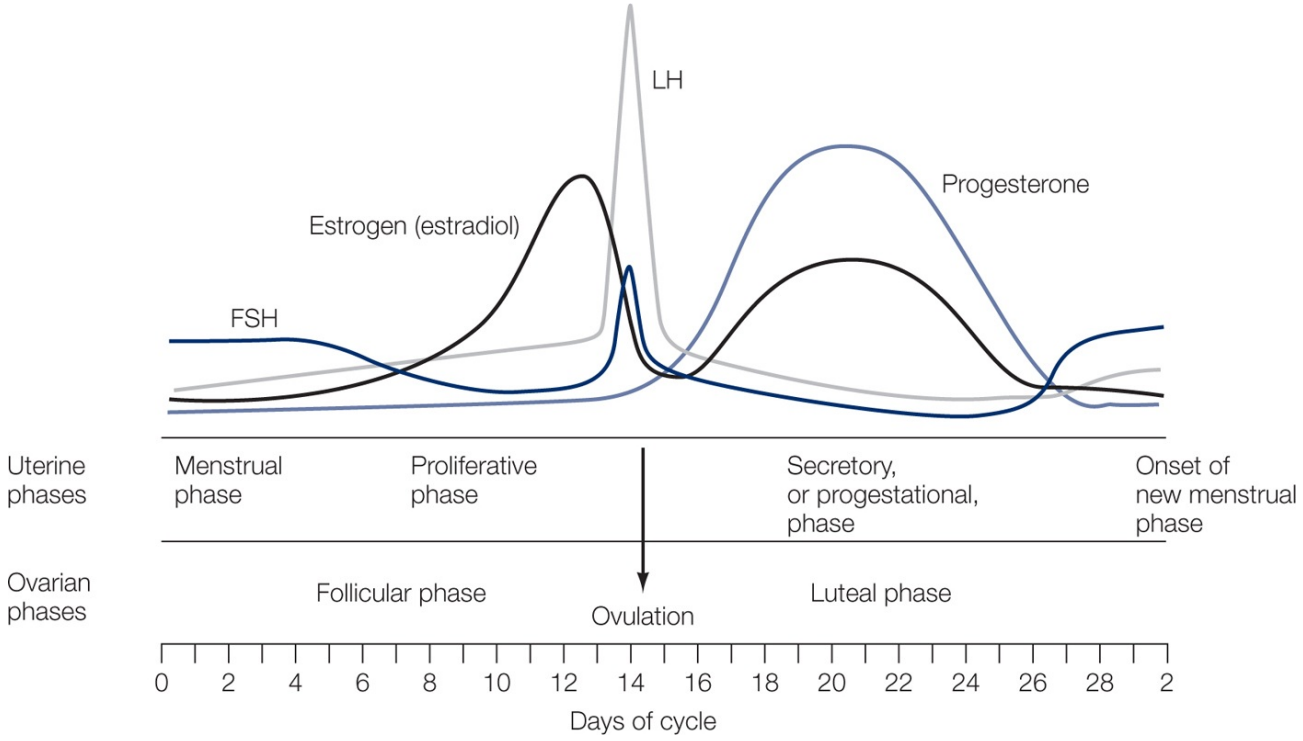

Figure 10-15 Hormonal changes throughout the menstrual cycle.

Abbreviations: FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Ovulation

Ovulation, as defined by release of the ovum, usually occurs 10 to 12 hours after the LH peak and 24 to 36 hours after the estrogen surge. No one single event causes ovulation. The oocyte is released with the cumulus oophorus and antral fluid. The fimbria of the ovary sweeps by and catches the ovum within the fallopian tube. Some women experience discomfort, known as mittelschmerz, at this time. The remaining follicular cells (granulosa and theca cells) in the ovary are transformed into a structure called the corpus luteum (yellow body), which grows for at least a week and forms a mature corpus luteum. If fertilization does not occur, the corpus luteum begins to degenerate into the corpus albicans.

The LH surge is the most reliable single indicator of ovulation.[33] Likely to last for 48 hours or longer, it promotes luteinization of the granulosa cells in the follicle and the synthesis of prostaglandins and other eicosanoids needed for follicle rupture. Progesterone levels continue to rise with the LH surge and may, with the FSH peak that accompanies the peak of LH, be part of the termination of the event. Low levels of progesterone contribute to LH and FSH peaks, whereas high levels can prevent LH surge. Progesterone works with prostaglandins to enhance digestion of the follicle's wall, thereby promoting ovulation. High levels of intrafollicular prostaglandins may cause the oocyte to be retained. These physiologic events form the basis for some theories regarding the decrease in ovarian cancer associated with use of oral contraceptives. Appropriate surges mean nothing if the dominant follicle is not present, and without the mature preovulatory follicle it is likely that the surges may not occur. These kinds of complex interdependencies characterize ovarian cycle processes.

Other physiologic events accompany ovulation. For example, under the influence of estrogen in the mid- to late follicular phase, the cervical mucus becomes clear, thin, and more profuse; the cervix softens; and the external os opens slightly. These changes in cervical mucus facilitate sperm transport. After ovulation, higher progesterone levels lead to the production of thick cervical mucus, which inhibits the entry of sperm into the uterus.

Luteal Phase

A luteinized granulosa cell is able to produce both estradiol and progesterone. An older, and less nuanced, description of the menstrual cycle implied that progesterone was produced only after ovulation. Increases in progesterone levels may be noted as early as day 10 of the cycle, although progesterone production rises sharply after ovulation and peaks at 8 days after the LH surge. Progesterone suppresses new follicular growth.

Whereas the length of the follicular phase of the ovarian cycle may vary, the duration of the luteal phase essentially remains constant at 14 days. This length of time is directly related to corpus luteum longevity, assuming no interference by conception. In the luteal phase, estrogen is still produced and may facilitate destruction of the corpus luteum. Because progesterone is associated with an elevation in basal body temperature (BBT), daily measurement of BBT will demonstrate a rise *after* ovulation has occurred. This makes assessment of thermal activity useful as a post hoc measure and as the basis of some natural family planning methods. A variety of other factors, including oxytocin, are likely to be involved in this period.

Luteal–Follicular Transition Period

During the luteal–follicular transition, the corpus luteum dies and estrogen, progesterone, and inhibin levels decrease such that there is transitional time between one cycle and the next. Because production of inhibin A drops, FSH levels begin to increase. Conversely, because estrogen and progesterone levels are low, GnRH pulses increase, which in turn facilitates production and release of FSH and LH from the hypothalamus and pituitary. FSH helps a group of follicles to be rescued from atresia, and the cycle to begin anew.

The Endometrial Cycle

Many sources subdivide the endometrial cycle into two periods: proliferative and secretory. Other authorities note that ischemic changes occur at the end of the secretory phase, with this ischemic period being designated as a separate phase. Still other sources identify menses as a first phase of the endometrial menstrual cycle (**Figure 10-16**).

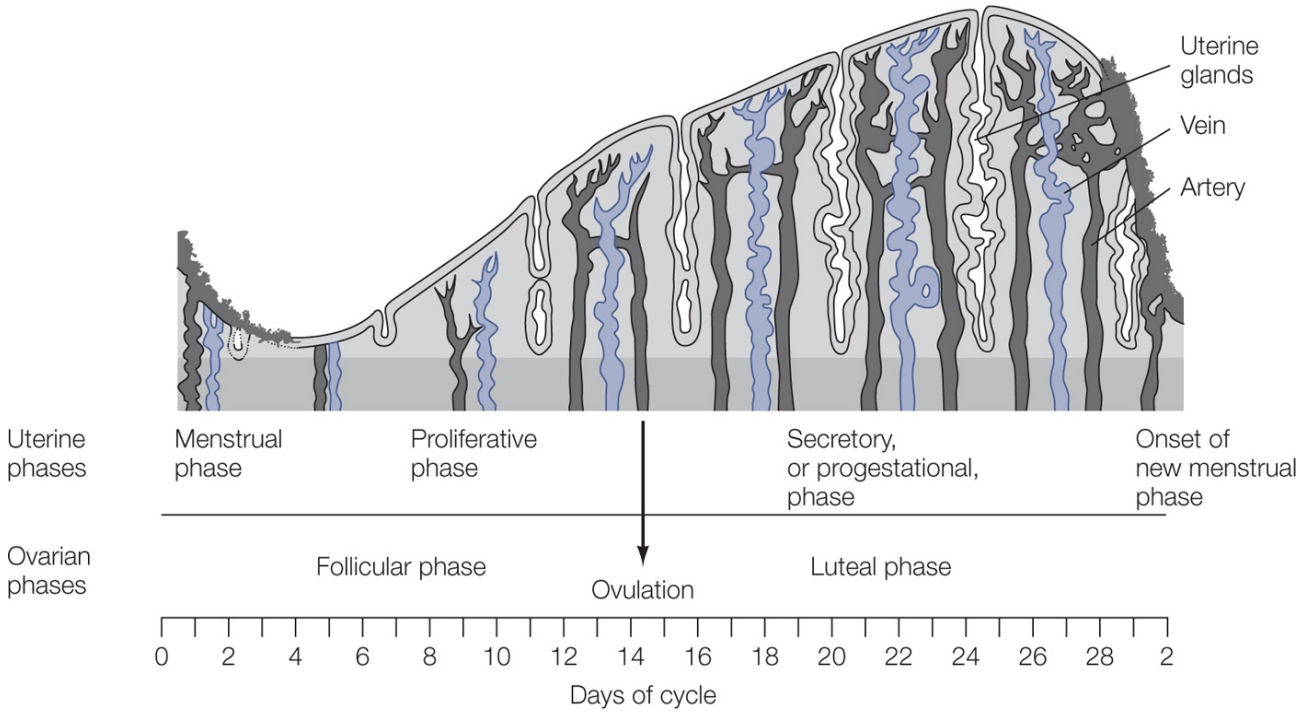

Figure 10-16 The endometrial cycle.

Proliferative Phase

The proliferative phase of the endometrial cycle corresponds to the follicular phase of the ovarian cycle. During this time the endometrial tissue develops under the increasing influence of estrogen. Endometrial glands change from being narrow and tubular to being enlarged to an extent that they link to each other, forming a continuous lining.

In rare situations, such as during unopposed treatment with exogenous estrogen or among women with anovulation, a proliferative endometrium becomes persistent. When this occurs, there is a higher risk that endometrial hyperplasia will ensue; this state is associated with endometrial cancer. These conditions are discussed in more detail in the *Menstrual Cycle Abnormalities* chapter.

Secretory Phase

The rising progesterone levels that occur with ovulation have a major influence on the endometrium, turning a proliferative endometrium into a secretory one. The length of the endometrium does not regress, but the appearance of the tissue does. Notably, the coiling of spiral vessels and tortuosity of the glands increase. The stroma become edematous and at the

time of implantation, approximately days 21–27 of the cycle, three distinct zones have appeared: the stratum spongiosum (the most superficial layer), the stratum compactum (midportion), and the stratum basale (the innermost layer). Once an endometrium becomes secretory, the risks associated with persistent proliferative endometrium are diminished. Since the discovery that exogenous progesterone facilitates development of a secretory endometrium, it has become standard practice for women on perimenopausal hormone therapy to also take progesterone as an adjunctive treatment with the estrogen.

Ischemic Period

By approximately cycle day 25, if implantation does not occur, the decreasing levels of estrogen and progesterone result in disorganization of the endometrium. The tissue shrinks, venous drainage diminishes, and blood flow within the spiral arteries is compromised, resulting in rhythmic constriction and relaxation. The process of apoptosis transpires and the uterus is ready for the next step—menses.

Menstruation

As the lining of the uterus weakens, blood escapes into the endometrial cavity. The appearance of blood for the woman marks the first day of her next menstrual period. The consistency of bleeding after the withdrawal of estrogen and progesterone is indicative of a normal menstrual cycle with functional organs and endocrine system.

Investigation of amenorrhea often involves a challenge test in which women are given progesterone to ascertain whether, after completion of the dose, withdrawal bleeding occurs. If so, the assumption is made that there is no end-organ disorder and there is adequate endogenous estrogen. More information about this testing is found in the *Menstrual Cycle Abnormalities* chapter.

Considering that menstruation is a normal event experienced daily by millions of women around the world, it is somewhat surprising that much remains unknown about the physiology of this event. It is a testament to the remarkable innate capacities of the female body that in spite of the complexity of the menstrual cycle, the vast majority of women's menses occur on a regular basis without major mishap. **Figure 10-17** depicts the full menstrual cycle, including the ovarian, hormonal, and uterine cycles, in one illustration.[34] **Table 10-4** provides an overview of the menstrual cycle, including sequencing of the major events.

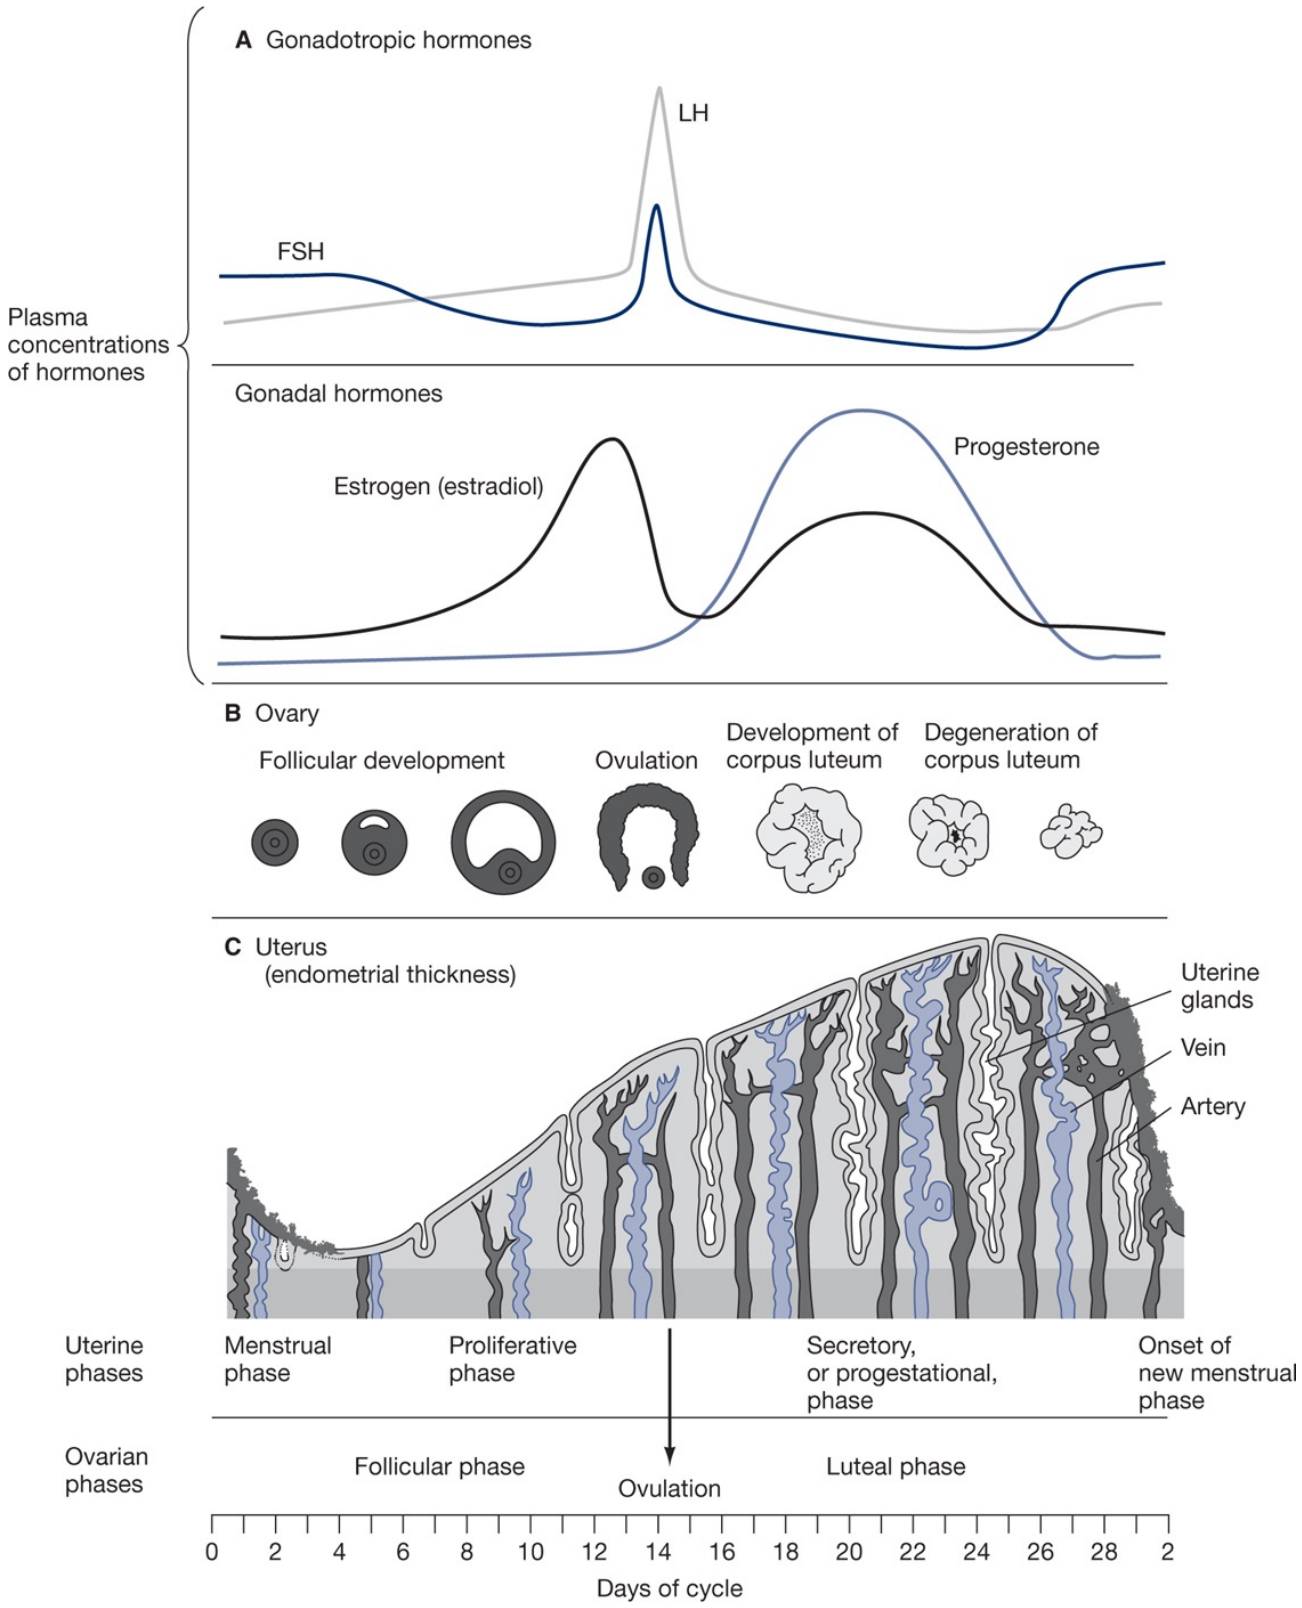

Figure 10-17 The menstrual cycle. **A.** Hormonal cycles. **B.** The ovarian cycle. **C.** The uterine (endometrial) cycle.

Abbreviations: FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Table 10-4 Overview of the Menstrual Cycle

Days	Ovarian Cycle	Endometrial Cycle	Estrogen and Progesterone	Actions
1–5	Follicular	Menstrual	Low estrogen and progesterone	Inhibin falls. LH and FSH begin to slowly rise, starting on approximately day 27.
6–14	Follicular	Proliferative	Building estrogen (and, to a lesser extent, progesterone)	LH initiates luteinization and progesterone production in the granulosa layer. The rising level of progesterone facilitates the positive feedback action of estrogen and may be necessary for the midcycle FSH peak, although the complete reason for the midcycle FSH peak remains unclear. Estrogen production becomes sufficient to achieve and maintain the threshold concentration of estradiol that is required to induce the LH surge. A midcycle increase in local and peripheral androgens occurs, derived from the thecal tissue of unsuccessful follicles. A few hours after the LH surge, changes in hormone levels release suppression of oocyte maturation.
14	Ovulation	Proliferative	High estrogen and building progesterone	High levels of estrogen induce the LH surge at midcycle and lead to sustained elevated LH secretion. Suppression of inhibition of oocyte maturation allows final maturation of the oocyte. The LH surge occurs and is responsible for luteinization of the granulosa, and synthesis of progesterones and prostaglandins in the follicle. Progesterone and prostaglandins work together to digest, weaken, and eventually rupture the follicular wall. The midcycle FSH peak frees the oocyte from follicular attachments and ensures sufficient LH receptors to allow an adequate normal luteal phase.
15–26	Luteal	Secretory (implantation phase)	Progesterone most dominant, but estrogen present	Progesterone from the corpus luteum acts both centrally and within the ovary to suppress new follicular growth. High levels of progesterone inhibit pituitary secretion of gonadotropins by inhibiting GnRH pulses at the level of the hypothalamus. High levels of progesterone antagonize the pituitary response to GnRH by interfering with estrogen action. Regression of the corpus luteum may involve luteolytic action of its own estrogen production, mediated by an alteration in local prostaglandin concentration. In early pregnancy, hCG maintains luteal function until placental steroidogenesis is established.
27–28	Luteal	Late secretory (ischemic)	Dropping estrogen and progesterone	The degeneration of corpus luteum results in low levels of estrogen, progesterone, and inhibin. The low level of inhibin removes the suppression of FSH on the pituitary. The low level of estrogen and progesterone allows an increase in GnRH pulsatile secretion and the removal of the pituitary from the negative feedback suppression. The removal of inhibin and estradiol and increased GnRH pulses allow an increase in FSH (and to lesser extent LH). The increasing FSH is instrumental in the maturation of a dominant follicle.

Abbreviations: FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone.

Female Sexual Response

The female sexual response is a complex interaction between mental processes and physical stimulation that has an infinite number of individual variations. The term “sexarche” designates the age of initial sexual intercourse although sexual activity can include many different expressions. Although this section describes the physiologic response, it is important to recognize that individual sexuality and individual sexual responses cannot be adequately described by knowing the basic physiology of the female sexual response. The entire areas of human sexuality and behavior have not been the subject of significant scientific research.

Sexual activity may have many components. From a physiological standpoint, the female sexual response has four primary phases, as shown in **Table 10-5**.[35,36] This model was originally developed by Masters and Johnson, who labeled the four phases as excitement, plateau, orgasm, and resolution.[35] A newer model developed by Basson et al., which incorporates emotional, cognitive, and psychological factors, has expanded understanding and provides a more detailed template for elucidating this complex phenomenon (**Figure 10-18**).[37] Notably, female orgasm is considered just one aspect of the female sexual response. The four phases outlined in Table 10-5 may overlap, repeat, or be absent. In addition, women do not always progress through these phases in the same sequence.[38]

Table 10-5 **Model for Female Sexual Response**

Stage	Description
Desire	Desire to have sexual activity; sexual thoughts and images present.
	Vaginal lubrication.
	Inner two-thirds of vagina expands, and vagina becomes lubricated. The cervix and uterus are pulled forward; the labia majora become flatter and, in parous women, increase in size. The labia minora enlarge.
	Blood flow to genitals increases and the erectile tissue of the clitoris expands.
	Nipples become erect and breasts slightly increase in size.
	Some increase in heart rate, respiratory rate, blood pressure, and muscle tension occurs.
	Vasocongestion of skin, called “sex flush,” occurs in 50–75% of women.
Arousal	Sense of sexual pleasure with physiologic changes.
	The inner-two thirds of the vagina expands as the uterus is elevated (called tenting). The outer third of the vagina becomes congested and the opening narrows.
	The labia minora and labia majora become engorged and enlarged.
	The clitoris withdraws into the clitoral hood.
	The breasts enlarge and blood flow to areola increases.
	A blotchy skin pattern may be seen as sex flush.
	Further increases occur in heart rate, respiratory rate, and blood pressure.
Orgasm	Peaking of sexual pleasure.
	Rhythmic muscular contractions of the uterus, outer third of the vagina, anal sphincter, and clitoris occur.
	Heart rate, respiratory rate, and blood pressure are at their highest values.
	Other muscles, such as those in the buttocks or feet, may involuntarily contract.

Resolution	Sense of well-being.
	If continued sexual stimulation and interest, multiorgasmic response is possible; if not, the organs return to their unaroused state.
	Vasocongestion dissipates; the uterus, vagina, and clitoris return to their normal size and position.
	The breasts decrease in size; the areola and nipples flatten.
	Breathing, heart rate, and blood pressure return to normal.

Based on Masters WH, Johnson VE. *Human Sexual Response.* New York, NY: Bantam; 1966[35]; American Psychiatric Association. Sexual dysfunctions. In: *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013:423-450.[36]

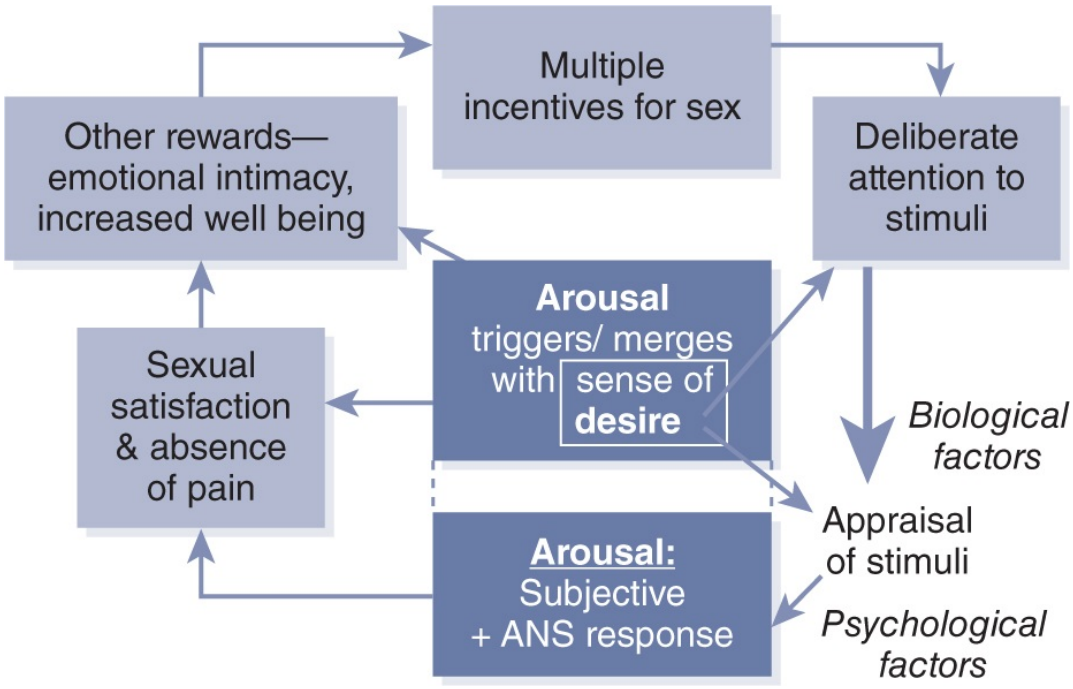

Figure 10-18 Human sexual response is depicted as a motivation/incentive-based cycle of overlapping phases of variable order. A sense of desire may or may not be present initially; it can be triggered alongside the sexual arousal resulting from attending to sexual stimuli. Sexual arousal comprises subjective and physical responses. Psychologic and biologic factors influence the brain's appraisal of the sexual stimuli. The sexual and nonsexual outcomes influence present and future sexual motivation.

Abbreviation: ANS, autonomic nervous system.
Reproduced with permission from Basson R. Human sexual response. *Handbook Clin Neurol.* 2015;130:11-18.[37]

Orgasm may be stimulated by vaginal penetration or clitoral stimulation, although it may also occur without these actions. In general, clitoral stimulation is the most common source of physical stimulation for initiation of orgasm. One interesting controversy about the anatomy of the female sexual response is the "G-spot," which is a presumed anatomic collection of nerves in the anterior vagina that is the source of vaginally stimulated orgasm. Subsequent anatomic and physiologic studies have not confirmed that this spot exists.[38,39]

Orgasm is regulated by both sensory and autonomic nerves. It starts when the pudendal nerve transmits information from the clitoris and external genitalia; this is followed by increased blood flow to the area. A reflex wave of smooth and skeletal muscle contractions then occurs in the vagina, urethra, anus, and uterus.

Estrogen—in particular, estradiol—is the primary hormone that mediates the female sexual response, but the roles of the hormones of import are not fully understood. However, the lower levels of estradiol that occur following menopause are the etiology of vaginal atrophy, as well as difficulty with vasoconstriction and vaginal lubrication. These changes associated with aging can lead to diminished sexual interest, arousal, and orgasm.[40]

Conclusion

This chapter presents a brief overview of the female reproductive anatomy and physiology. Midwives who will care for women with specific disorders such as pelvic floor dysfunction, sexual dysfunction, or menstrual disorders will need additional detailed knowledge about how the anatomy and physiology of these organs affect a woman's health. Some resources for reviewing these topics are included in the Resources section.

Introduction

Changes in the menstrual cycle can create a range of cultural, emotional, physical, and psychological concerns for women. There are many ways in which an individual views menstrual and reproductive cycles, which are taken into consideration when a midwife provides accurate and relevant information for shared decision making. Acknowledging the normalcy of variation in menstrual cycles provides a framework within which individuals and midwives can identify and address abnormal changes should they occur. This chapter addresses the complex condition of amenorrhea as well as the different bleeding patterns associated with abnormal uterine bleeding (AUB). A discussion of dysmenorrhea, or painful menses, completes the chapter.

The Normal Menstrual Cycle and Variations

A wide variation in menstrual cycles exists, with only 15% of reproductive-age women reporting a cycle of 28 days.[1] The average range is 21 to 34 days and may vary between 2 and 20 days over a 12-month period.[2] The average duration of bleeding is 4.5 to 8 days. The amount of blood loss considered normal during menses has been described as approximately 30 mL based on research conducted in the 1960s, with anything more than 80 mL deemed abnormal.[1] However, it is common to either over- or underestimate the amount of menstrual bleeding that occurs on a monthly basis.[2] Additional information about the menstrual cycle is found in the *Anatomy and Physiology of the Female Reproductive System* chapter.

The onset of menstruation, termed *menarche*, occurs usually between 11 and 13 years (median age is 12.4 years), which is 2 to 3 years after thelarche (breast budding). The initial bleeding is usually anovulatory and unpredictable.[1,2] Cycles become regular and of the normal adult frequency by the third year after menarche.[2] By late adolescence, the typical ovulatory menstrual pattern is predictable in cycle regularity within a few days, and may be accompanied by mild dysmenorrhea. A few individuals also experience mild discomfort or sensation during ovulation, known as *mittelschmerz*.

Changes in menstrual cycle length are primarily due to differences in the follicular phase of the ovarian cycle; by comparison, the luteal phase tends to remain consistent. Women in their late 30s typically experience slightly shorter and less variable menstrual cycles than younger women due to increases in follicle-stimulating hormone (FSH) levels and decreases in inhibin levels, which results in a shorter follicular phase.[1]

Cycles typically lengthen again 2 to 4 years prior to menopause, followed by a complete cessation of menstruation. Menopause occurs at a median age of 51 years, with the range being 45 to 55 years.

Thus, the greatest fluctuation in duration of menstrual cycles occurs at either end of the reproductive spectrum, primarily due to an increase in anovulatory cycles among women younger than 20 years and those older than 40 years.[2] Because there can be a great deal of normal variation in the menstrual cycle in the early and later reproductive years, the initial steps in clinical evaluation of anyone who has menstrual irregularities differs for (1) adolescents, (2) women of reproductive age, and (3) those who are entering the menopausal transition. This distinction by age and proximity to menarche or menopause is always one of the initial considerations that is factored into the evaluation.

Many people describe any bleeding as a “period,” and some automatically interpret any blood found in underwear or on toilet tissue as of vaginal origin. For example, withdrawal bleeding associated with combined oral contraceptives may be mischaracterized by users as a menses. Nevertheless, an important distinction should be made between “menstrual bleeding” that occurs as a component of the menstrual cycle, even if it may vary in timing and amount, and AUB, which occurs independent of the menstrual cycle. **Table 11-1** reviews menstrual cycle parameters, and **Table 11-2** provides a glossary of terms used to describe forms of AUB.[3-6]

Table 11-1 Definitions of Terms to Describe Menstrual Irregularities

Description	Quantification
Frequency of Menses	
Absent	Amenorrhea
Frequent	More often than every 24 days
Normal	Occurs between 24–38 days
Infrequent	Less often than every 38 days
Regularity: Cycle to Cycle	
Regular	Variation of 2–20 days[a]
Irregular	Variation of > 20 days[a]
Duration of Menses	
Prolonged	> 8 days
Normal	4.5–8 days
Shortened	< 4.5 days
Volume per Menses	
Heavy	Volume that interferes with the woman's physical, social, emotional and/or material quality of life Menstrual blood loss of ≥ 80 mL
Normal	5–80 mL
Light	< 5 mL

[a] Normal variation in menstrual cycle regularity depends on age.

Table 11-2 Glossary of Terms That Define Menstrual Abnormalities and Abnormal Menstrual Bleeding

Term	Description
Abnormal uterine bleeding (AUB)	Any variation from the normal menstrual cycle Changes include those in regularity, duration of flow, amount of flow, and frequency of flow
AUB: Acute	An episode of bleeding in an individual of reproductive age, who is not pregnant, of sufficient quantity to require immediate intervention to prevent further blood loss
AUB: Chronic	Bleeding from the corpus uterus that is abnormal in duration, volume, and/or frequency that has been present for the majority of the last 6 months
AUB: Intermenstrual	Bleeding between clearly defined cyclically predictable menses
Amenorrhea	No menses for ≥ 3 previous consecutive months

	Subclassified into primary (prior to menarche) or secondary (post menarche)
Heavy menstrual bleeding (HMB)	Excessive menstrual blood loss (≥ 80 mL/cycle), which interferes with a person's physical, social, emotional, and/or quality of life
Heavy and prolonged menstrual bleeding (HPMB)	Heavy menstrual bleeding lasting > 8 days
Irregular menstrual bleeding	Range of varying lengths of bleeding-free intervals of > 20 days within one 90-day reference
Infrequent menstrual bleeding	Bleeding at intervals > 38 days apart (1–2 episodes in a 90-day period)
Frequent menstrual bleeding	Bleeding at intervals < 24 days apart (> 4 episodes in a 90-day period)
Prolonged menstrual bleeding	Menstrual blood loss which exceeds 8 days in duration
Shortened menstrual bleeding	Menstrual bleeding < 3 days in duration
Irregular, nonmenstrual bleeding	*Intermenstrual: Irregular episodes of bleeding, often light and short occurring between otherwise normal menstrual cycles*
	Postcoital: Bleeding after intercourse
	Premenstrual and postmenstrual spotting: Bleeding that may occur on a regular basis for ≥ 1 days before or after the recognized menstrual period
Bleeding outside of reproductive age	Postmenopausal bleeding: Bleeding occurring > 1 year after the acknowledged menopause
	Precocious menstruation: Bleeding occurring before the age of 9 years

Based on Fraser IS, Critcheley HOD, Broder M, Munro MG. The FIGO recommendations on terminologies and definitions for normal and abnormal uterine bleeding. *Sem Reprod Med.* 2011;29(5):383-391[3]; Munro MG. Practical aspects of the two FIGO systems for management of abnormal uterine bleeding in the reproductive years. *Best Pract Res Clin Obstet Gynaecol.* 2017;40:3-22.[4]

Amenorrhea

Amenorrhea is the absence of menses or menstrual bleeding.[7,8] Amenorrhea is further categorized as *primary* or *secondary* based on occurrence prior to or after menarche, respectively.[7-9] Although some causes of primary amenorrhea are distinct, most of the causes of secondary amenorrhea can also be the etiology of primary amenorrhea. Furthermore, amenorrhea can be the result of common events such as pregnancy, lactation, menopause, use of hormonal contraception, or the result of a pathologic condition. Both normal and pathologic causes of amenorrhea involve a disruption in the hypothalamic–pituitary–ovarian (HPO) axis or anatomic anomaly within the outflow tract. Thus, it is helpful to consider five possible categories when evaluating causes of amenorrhea: (1) outflow tract abnormality; (2) ovarian disorder; (3) pituitary disorder; (4) hypothalamus disorder; or (5) endocrine disorder that interferes with the HPO axis.

The list of differential diagnoses for amenorrhea is long. However, the majority of women who have amenorrhea that is not related to a normal condition (e.g., pregnancy, menopause, hormonal contraception, or lactation) have one of the following four disorders: (1) polycystic ovary syndrome; (2) hypothalamic amenorrhea (i.e., amenorrhea without an organic cause secondary to an eating disorder, stress, or excessive exercise); (3) hyperprolactinemia; or (4) primary ovarian insufficiency (also referred to as premature ovarian failure, premature menopause, gonadal dysgenesis).[7]

The etiologies unique to primary amenorrhea include anomalies of the outflow tract, genetic disorders that affect gonadal function such as Turner syndrome, and central anomalies of the HPO axis.[7-9] Approximately 30% to 40% of adolescents with primary amenorrhea are found to have Turner syndrome (45,XO karyotype).[9,10] The next most common causes of primary amenorrhea are structural abnormalities of the outflow tract (uterus, vagina, hymen) and central HPO axis anomalies.

Table 11-3 lists differential diagnoses associated with amenorrhea.

Table 11-3 Classification of Causes of Amenorrhea

Category	Examples
Expected physiologic findings	Pregnancy, lactation, hormonal contraceptive use, menopause
Outflow tract defects	Congenital: Müllerian agenesis, vaginal septum, imperforate hymen
	Acquired: Cervical stenosis, Asherman syndrome
Primary hypogonadism: ovarian insufficiency or ovarian failure	Congenital (e.g., Turner syndrome, Müllerian agenesis, gonadal dysgenesis, imperforate hymen, vaginal septum)
	Acquired (e.g., chemotherapy, autoimmune disorder); primary ovarian insufficiency
Hypothalamic disorders	Functional hypothalamic amenorrhea (secondary to weight loss, eating disorder, excessive exercise, stress, rarely pseudocyesis), gonadotropin deficiency, infection, chronic debilitating disease, malabsorption, traumatic brain injury, tumor
Pituitary disorders	Prolactinomas, hormone secreting pituitary tumor, autoimmune disease, Cushing syndrome, medications, Sheehan syndrome

Endocrine disorders	Polycystic ovary syndrome,[a] thyroid dysfunction, adrenal disease (Cushing syndrome), ovarian tumors

[a] Polycystic ovary syndrome is sometimes categorized as a sixth category termed “multifactorial” because several abnormalities of the hypothalamic–pituitary–ovarian axis are involved in this disorder.

The definition of *primary amenorrhea* is not standardized. One definition is the absence of menses by age 15 years in young women with developed secondary sex characteristics, within 5 years after breast development if breast development occurs before age 10 years, or if there is no pubertal development by age 13 years.[7,9] Another definition is a more relative description based on time from appearance of secondary sexual characteristics. Using this definition, primary amenorrhea is lack of menarche within 3 to 5 years of thelarche (Tanner breast stage II development) or by the age of 15 to 16 years regardless of the presence of secondary sex characteristics. Age at menarche of other family members may be helpful in determining whether the initiation of menses is within normal parameters for the individual.

Secondary amenorrhea is defined as absence of menses for 3 months in a previously menstruating woman or for 9 months in a woman who has experienced previous irregular menses with fewer than nine cycles in a year.[7,11] The incidence of secondary amenorrhea unrelated to pregnancy is approximately 5%, but rises to 80% in some populations, including those diagnosed with the female athlete triad (addressed later in this chapter).[7,9,12,13]

Evaluation for a Woman with Amenorrhea

The assessment of someone with amenorrhea starts with a determination of primary versus secondary amenorrhea and secondly consideration of age and proximity to menarche or menopause. These distinctions will direct the focus of the history and physical examination. The list of possible etiologies of amenorrhea is long and multiple different algorithms exist for evaluation this condition. **Figure 11-1** provides a representative example of the common steps involved in the initial evaluation. Follow-up tests to assess for specific disorders are recommended after initial screening to identify the most likely category of etiologies.

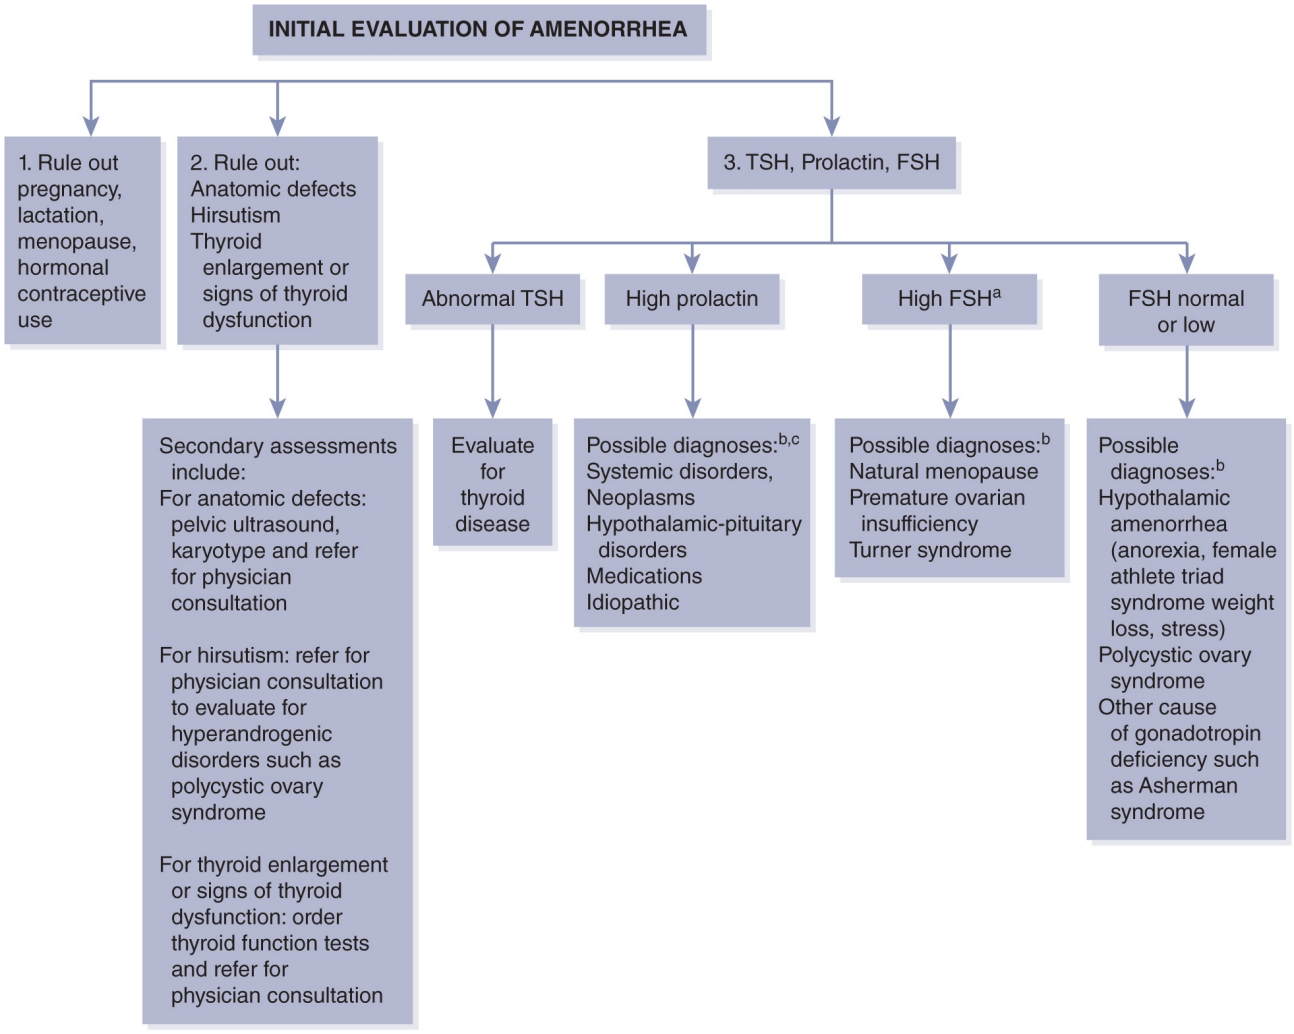

Figure 11-1 Initial evaluation of amenorrhea and common etiologies.

Abbreviations: FSH, follicle-stimulating hormone; MRI, magnetic resonance imaging; TSH, thyroid stimulating hormone.

[a] Some clinicians add a test for estradiol and/or luteinizing hormone to this initial evaluation.

[b] This list of diagnoses reflects common diagnoses and is not a complete list of the diagnoses possible.

[c] Prolactinemia can be secondary to many different disorders, including systemic disease, hypothalamic-pituitary disorders, medication use, or neoplasm. Prolactinemia may also be idiopathic. Approximately 50–60% of women with a high prolactin level have a pituitary tumor. The standard follow-up examination is an MRI.

Primary amenorrhea: diagnosis and management. *Obstet Gynecol Surv.* 2014;69:603-612[8]; Klein DA, Poth MA. Amenorrhea: an approach to diagnosis and management. *Am Fam Phys.* 2013;87(11):781-788.[11]

History and Physical Examination

When initiating an evaluation of a woman with amenorrhea, a thorough history and physical examination are required. A detailed menstrual and family history will establish primary versus secondary amenorrhea and can provide insight into any familial patterns of irregular menses or early menopause. The history should also include information about use of hormonal

contraception, any change in overall health status, current and past medications, galactorrhea, presence of premenopausal symptoms, increase in stress levels, eating and exercise patterns, and any physical or emotional trauma.

The physical examination includes an assessment of body mass index (BMI), breast development (an indicator of previous estrogenic influence) and an evaluation of the presence of hirsutism or extensive muscle mass, both of which are suggestive of excessive testosterone levels. Thyroid palpation may detect possible thyroid dysfunction. External and internal genitalia should be thoroughly assessed for structural anomalies such as a blind or absent vagina. The findings of a genital examination will be abnormal in an estimated 15% of women with amenorrhea.[7] For most women with amenorrhea, the findings on physical examination will be normal, and the evaluation continues with an assessment of laboratory data.

Laboratory Studies

If the history and physical examination do not detect signs of congenital abnormalities, the next step for all women (unless the individual is postmenopausal) is to rule out pregnancy because pregnancy remains the most common reason for amenorrhea and results of this test will directly influence the next steps in evaluation. Once pregnancy is ruled-out, initial laboratory testing for FSH level, thyroid-stimulating hormone (TSH), and prolactin level will generate results that guide the rest of the evaluation. Other tests that may be indicated include pelvic ultrasound, especially in the event of nonpalpable ovaries. Such imaging provides information about structural and congenital abnormalities and endometrial thickness. Magnetic resonance imaging (MRI) is indicated if a pituitary tumor is suspected. The complex relationship of the HPO axis to menstruation can be challenging to assess. The midwife may initiate the evaluation to establish the category of possible diagnoses, but after the initial evaluation, consultation with and referral to a reproductive endocrinologist is recommended to ensure appropriate diagnosis and management.

High FSH levels suggest ovarian problems whereas low or normal FSH levels indicate either pituitary or hypothalamus problems. Elevated FSH levels in the absence of secondary sex characteristics indicate a functioning hypothalamus but lack of ovarian function which could be secondary to natural or premature menopause, or a genetic disorder such as Turner syndrome. Normal or low FSH levels in persons with secondary sexual development (with or without signs of hyperandrogenism) may indicate hypothalamic amenorrhea, polycystic ovary syndrome, or other rare causes of gonadotropin deficiency.

Elevated prolactin levels (typically > 100 ng/L) with or without headache or visual changes may indicate a pituitary adenoma and in an indication imaging (MRI) to evaluate the pituitary. Prolactin suppresses release of gonadotropin-releasing hormone (GnRH) and hyperprolactinemia can develop at any point of sexual development. Subclinical or overt hypothyroidism can also affect ovulatory function. Elevated TSH levels suppress GnRH release either directly or by causing increased prolactin release. Prolactin inhibits GnRH as part of a physiologic negative feedback mechanism.

Hormonal Challenge Testing (Progesterone Challenge, Estrogen/Progestin

Challenge)

Historically a progesterone challenge test was included in the evaluation of women with amenorrhea but current bioassays are sensitive tests and withdrawal bleeding correlates poorly with estrogen status and therefore many experts no longer use this test as part of an initial evaluation.[7,14]

Evaluation of a Young Person with Primary Amenorrhea

The most common causes of primary amenorrhea can be identified by performing a physical examination to determine the presence of secondary sex characteristics or structural anomalies, rule out pregnancy, and assess the HPO axis through measurement of FSH, TSH, and prolactin levels.[9-11] The work-up begins with a thorough history, including review of any sexual activity, age at menarche for the adolescent's mother, and any underlying conditions, medications, lifestyle, or nutritional deficits that may affect the menstrual cycle, including recent onset of headaches or visual disturbances.[1,9,15] When assessing adolescent sexual activity, it is advised to engage in a private conversation away from family or anyone who may prevent open communication or pose a threat. Issues of suspected sexual or physical abuse, use of recreational drugs, or other risk-taking behaviors should also be assessed in a private space and addressed as appropriate.

A thorough physical examination assessing sexual development, presence of galactorrhea, external genitalia, presence of pelvic organs, and any evidence of outflow tract anomalies is essential. Sensitivity to the fact that this may be the first such examination an adolescent may have experienced is important in building rapport and being able to conduct a thorough assessment.

A young person with primary amenorrhea requires care from a specialist. If secondary sex characteristics are not present, a bone age may need to be determined. Elevated FSH levels indicate the need for karyotyping to further investigate reasons for ovarian dysfunction. Therefore, the skills of a midwife may best be employed to interact with the adolescent and to refer her to appropriate care for this condition.

Management of women with secondary amenorrhea largely focuses on treatment of the underlying etiology and midwives are often involved in initial assessment and primary care for these women. The conditions seen most frequently in women of reproductive age are polycystic ovary syndrome and functional hypothalamus amenorrhea.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS)—the most common diagnosis implicated in infertility related to ovarian dysfunction—is also the most common endocrine disorder in women with a prevalence of approximately 6% to 10% of the female population, depending on the population studied.[16,17] The incidence varies according to the criteria used to diagnose the condition. Historically, this condition was termed Stein–Leventhal syndrome, but later was renamed more descriptively as polycystic ovary syndrome.

PCOS is characterized by menstrual dysfunction, hyperandrogenism, and ovulatory

disruption.[16-18] The three classic features are hirsutism, irregular menstrual cycles and obesity. While amenorrhea is common in conjunction with this syndrome, menstrual cycle disruption is just one aspect of PCOS. Women with PCOS are often insulin resistant and are at increased risk for type 2 diabetes. Acanthosis nigricans—a brown velvety appearance to the skin in various folds, such as the back of the neck, in the axillae, under the breasts, or in the groin is a marker of insulin resistance and appears in some individuals with PCOS.[19,20] Polycystic ovaries are common in women with PCOS but can be seen in women without this disorder, so by itself, this finding is somewhat nonspecific. Women with PCOS are also at increased risk for developing endometrial cancer, sleep apnea, steatohepatitis, and mood disorders.

The cause of PCOS remains unknown, but a finer recognition of the possible adverse long-term sequelae is emerging, resulting in greater attention to diagnosis and treatment.[21,22] For example, women with PCOS—even those who are not obese—may have significant insulin resistance and, therefore, are at a higher lifetime risk for the development of both type 2 diabetes and cardiovascular disease.[1,17,22] Chronic anovulation associated with PCOS can result in unopposed estrogen stimulation of the endometrium and hyperplasia.

Diagnosis of Polycystic Ovary Syndrome

Criteria for diagnosis of PCOS continue to be debated by international experts.[17,19,20, 23-25] The Rotterdam PCOS Consensus Group criteria listed in **Table 11-4** are currently recommended by the United States National Institutes of Health.[23,25] There is some suggestion that infrequent menses or episodes of amenorrhea must be present for at least 2 years after menarche or primary amenorrhea at 16 years to make this diagnosis.[17] Additionally, true hyperandrogenism should be documented through measurement of testosterone levels, rather than just signs of androgen excess such as acne.[17,21] The Rotterdam criteria recognize three distinct clinical phenotypes of PCOS:

Table 11-4 Rotterdam PCOS Consensus Group Criteria for Diagnosis of Polycystic Ovary Syndrome

Exclusion of other etiologies and two out of three of the following:
Oligo- and/or amenorrhea
Clinical and/or biochemical signs of hyperandrogenism
Polycystic ovaries and exclusion of other criteria

Abbreviation: PCOS, polycystic ovary syndrome.

Based on National Institutes of Health. Evidence-based methodology workshop on Polycystic Ovary Syndrome. December 3-5, 2012. Executive Summary. Available at: https://prevention.nih.gov/docs/programs/pcos/FinalReport.pdf. Accessed December 9, 2017.[25]

- Frank PCOS: Oligomenorrhea, hyperandrogenism and polycystic ovaries
- Ovulatory PCOS: hyperandrogenism, polycystic ovaries, and regular menstrual cycles.
- Nonpolycystic ovary PCOS: Oligomenorrhea, hyperandrogenism, and normal ovaries

The diagnostic criteria for PCOS are different in adolescents than in adults. Menstrual irregularities, multifollicular ovaries, and signs of androgen excess (e.g., acne) are common in adolescents.[21] Thus, current diagnostic criteria for adolescents focuses on evidence of ovulatory dysfunction and androgen excess.[21] Evidence of androgen excess in adolescents includes one or more of the following: moderate to severe hirsutism, persistent acne vulgaris that is resistant to topical treatments, and elevation of serum total and/or free testosterone level. The diagnosis of PCOS is not established until other causes of hyperandrogenism have been ruled out.

If the diagnosis is confirmed, assessment of a risk of diabetes or cardiovascular disease is warranted, including measurement of glucose, hemoglobin A1c (HbA1c), and lipid levels. Insulin resistance does not always reveal itself as elevated blood glucose levels or elevated HbA1c value, but more typically results in blood sugar spikes and abdominal obesity prior to elevation of glucose levels. On examination, an assessment of the woman's BMI, blood pressure, waist-to-hip circumference, and hirsutism should also be made. A waist-to-hip ratio of 0.85 or more indicates abdominal obesity and an increased risk for metabolic and cardiovascular conditions.[26]

Treatment for Persons with Polycystic Ovary Syndrome

Treatment of women with PCOS varies and often depends on the degree of infertility or desire for conception. In women who are obese the abnormalities associated with PCOS may be treated with weight loss and lifestyle changes alone, with the aim of improving insulin sensitivity. Subsequent significant weight loss has been observed to result in more normal ovulatory and menstrual patterns as well as unassisted conception.[27] The use of the anti-hyperglycemic drug metformin (Glucophage) has increased in popularity in recent years, although the effectiveness of this medication in women with PCOS is not clear.[27] Because there is an association between obesity and depression, a screening for depression may be warranted when caring for any woman who has a high BMI.

If conception is not desired immediately, ovarian function and continued physical enlargement of the ovaries may be suppressed with the use of combination hormonal contraceptives.[28] This temporary ovarian suppression optimally will result in the initiation of normal ovarian function for a short time upon discontinuation of the hormonal contraceptive. Use of a hormonal contraceptive method will also provide protection from the potential risks of unopposed estrogen stimulation of the endometrium, which might otherwise result in endometrial hyperplasia or even endometrial cancer. Additional information, including contraindications for the use of combined oral contraceptives, can be found in the *Hormonal Contraception* chapter.

Various medications, such as gonadotropin-releasing hormone (GnRH) agonists and the diuretic spironolactone (Aldactone), have also been employed as antiandrogens. Induction of ovulation, through administration of clomiphene citrate (Clomid), is a common strategy for the prompt treatment of women with infertility as a result of PCOS.[17,19,25] Women are best referred to a specialist for these treatments. **Table 11-5** provides a sample of the critical elements in a transfer or referral note to the specialist.

Table 11-5	Sample Critical Elements for a Transfer Note for an Individual with Possible Polycystic Ovary Syndrome
Menstrual history, including duration of amenorrhea and irregular menses	
Signs and symptoms suggestive of PCOS (e.g., hirsutism, obesity)	
Laboratory results or if pending, including pregnancy test, TSH, HbA1c, and sonography	
Care provided before transfer: procedures and results	
Assessment/diagnosis of the situation	
Summary of rationale for transfer and request for information about treatment plan for follow-up	

Abbreviations: HbA1c, hemoglobin A1c; PCOS, polycystic ovary syndrome; TSH, thyroid-stimulating hormone.

Early diagnosis and intervention for PCOS, with respect to the health risks of hyperglycemia, abnormal cholesterol and lipid profiles, and reproductive cancer risk, may positively influence overall health. In addition, mental health disruptions that may result from a diminished sense of self-esteem due to physical appearance and infertility require the midwife's attention.[17]

Functional Hypothalamic Amenorrhea

Functional hypothalamic amenorrhea can occur when the HPO axis is disrupted by nutritional deficiency, extreme weight loss, exercise, and stress; it is characterized by a chronic low estrogen state along with low to normal FSH levels in the absence of organic disease.[29,30] Women who experience functional hypothalamic amenorrhea have a functional disruption in the normal pulsatile GnRH secretion. The decreased pulses result in absent midcycle LH surge, anovulation, and amenorrhea. The diagnosis is made after excluding other organic disorders that cause amenorrhea. Low serum FHS and low estradiol levels in combination with the presence of precipitating factors such as excessive exercise, anorexia nervosa, stress, and weight loss are usually present. A progesterone challenge test may be indicated to confirm low estrogen status and lack of withdrawal bleeding.

Limited energy availability is associated with hypothalamic dysfunction, which adversely affects menstruation and bone health.[29,30] In contrast, functional hypothalamic amenorrhea is not necessarily associated with an eating disorder, although anorexia nervosa should be considered in the differential diagnosis. Weight loss and low energy may be present as a result of over-exercise and a lack of awareness that the woman is not taking in sufficient calories to support her energy expenditure. Menstrual function can be restored when the energy imbalance is addressed.

Treatment of women with this complex condition requires an interdisciplinary team approach that includes nutritional support, mental health services, and family support. Most importantly, the focus should center on the woman and her shared decision making about lifestyle choices. Treatment should include close monitoring for osteopenia or osteoporosis, as the hypo-estrogenic state may negatively influence bone density over time.[1,29]

Female Athlete Triad and Eating Disorders

Women who are diagnosed with functional hypothalamic amenorrhea should be assessed for the syndrome called *female athlete triad*, which can occur in women who are not elite athletes, and in persons with eating disorders, especially anorexia nervosa.[29,30] The female athlete triad is the result of energy imbalance affecting hypothalamic function and involves three components: (1) low energy availability with or without an eating disorder, (2) menstrual dysfunction, and (3) low bone density.[29] It is not necessary to have all three components present to recognize the triad. Any one of the three may be present individually or in combination.

Women who have anorexia nervosa may have many of the same symptoms as women with female athlete triad and women who have female athlete triad are at increased risk for eating disorders. The primary distinction between the two conditions is that individuals with anorexia maintain a low body weight, severely restrict nutritional intake, and have a fear of gaining weight. Anorexia is more common in younger adolescents in general. Amenorrhea may be present as well but anorexia is not always associated with excessive exercise.

Anorexia is associated with multiple endocrine abnormalities and more morbidity. The most common long-term risk for women with female athlete triad is osteoporosis. Because there is significant overlap between these two conditions, any woman who has symptoms of either should be referred to a physician and multidisciplinary team for further evaluation, diagnosis, and treatment. Midwives who participate in care of these women as part of an interprofessional team, will have additional training in the healthcare services needed by this population.

Hyperprolactinemia (Pituitary Adenoma)

Elevated prolactin levels can suppress the normal gonadotropin release necessary to stimulate ovulation, resulting in amenorrhea. Prolactin levels can be elevated by a number of conditions, including pituitary adenoma and prolonged hypothyroidism.[11] Other causes of elevated prolactin levels include use of medications such as tricyclic antidepressants and opiates that block dopamine receptors. Dopamine normally inhibits prolactin secretion, so anything that blocks dopamine can result in increased prolactin levels.[10] High prolactin levels much higher than the maximum of the normal range, which is 20 ng/mL, that may or may not be accompanied by visual changes or headaches may indicate the presence of a pituitary adenoma and require evaluation by MRI and an endocrinologist.[8],[10] Care of persons with hyperprolactinemia is best provided by specialists.

Rare Conditions Associated with Secondary Amenorrhea

Amenorrhea is also associated with premature ovarian insufficiency, autoimmune disorders, and ovarian tumors.[6,7] Premature ovarian insufficiency is the inability of the ovary to respond to gonadotropin stimulation, and is usually found in a woman 40 years or younger.[15] Premature ovarian insufficiency affects 0.5% to 3.0% of reproductive-age women.[15] This condition can result from natural causes, chemotherapy, radiation, extreme stress, other medications, or autoimmune causes.[1,7,31] Autoimmune disorders that are associated with premature ovarian

insufficiency include adrenal insufficiency (Addison's disease) and autoimmune thyroid disease (Graves' or Hashimoto disease); metabolic conditions (e.g., type 1 diabetes) may also cause secondary amenorrhea. Ovarian tumors can disrupt menstrual function by changing the responsiveness of the ovary to gonadotropins.

Less common conditions associated with amenorrhea include late-onset congenital adrenal hyperplasia, Cushing syndrome, adrenal and androgen-secreting tumors, Asherman syndrome, and Sheehan syndrome. Congenital adrenal hyperplasia may present later in a woman's life as increased androgen production and observable androgenic effects affect the normal menstrual cycle. Other hyperandrogenic states resulting from conditions such as Cushing syndrome and adrenal tumors affect the menstrual cycle by suppressing normal ovarian function through overproduction of androgens. Ovulation and menstruation often return after correction of the hyperandrogenic state.

Asherman syndrome is the development of intrauterine adhesions and/or fibrosis of the endometrium as a result of trauma, excessive instrument manipulation, or evacuation of the uterus.[14] The endometrium is not functional and does not respond to hormonal stimulation. The entire endometrium may not be affected, resulting in lighter than normal cyclical endometrial shedding versus complete amenorrhea.

Sheehan syndrome is ischemic necrosis of the pituitary gland, which usually occurs as a result of a profound postpartum hemorrhage.[14] Destruction of the pituitary gland results in amenorrhea, hypothyroidism, and impaired initiation of lactation.[14]

Complementary/Alternative Therapies for the Treatment of Women with Amenorrhea

Herbalists may recommend blessed thistle or blue cohosh for the relief of amenorrhea, while acupuncture and homeopathic remedies have been suggested as other treatment modalities.[32] To date, no published, evidence-based investigations have addressed the safety of using these remedies and effectiveness has not been conclusively demonstrated.

Abnormal Uterine Bleeding

AUB is an overarching term that refers to uterine bleeding that is abnormal in frequency, duration, regularity, and/or volume.[5,6,33] AUB affects as many as 30% of women at some point between menarche and menopause.[34-36] AUB can be acute or chronic. This condition is often subcategorized as anovulatory or ovulatory patterns. Anovulatory AUB is associated with prolonged unopposed estrogen stimulation of the endometrium and subsequent irregular bleeding. PCOS, thyroid dysfunction, hyperprolactinemia, uncontrolled diabetes, and use of some medications are typical causes of anovulatory AUB. Anovulatory AUB is associated with an increased risk for endometrial cancer. Ovulatory AUB is associated with heavy menstrual bleeding (menorrhagia) and can be caused by thyroid dysfunction, coagulation defects, endometrial polyps or uterine fibroids (submucosal).

In practice, women with AUB experience patterns of bleeding that encompass more than one of these categories. For example, a woman may experience heavy menstrual bleeding that is longer in duration and higher in volume than normal bleeding. Intermenstrual bleeding may be frequent and irregular. AUB also refers to any bleeding that occurs in a postmenopausal woman, as discussed in the *Midlife, Menopause, and Beyond* chapter.

Similar to the causes associated with amenorrhea, the most common etiologies of AUB differ by age. In adolescents younger than 18 years, AUB is often the result of anovulation that is secondary to dysregulation of the HPO axis and can be a normal physiologic finding. The second most common cause of AUB in this age group is an inherited coagulopathy.[33,34] In women between the ages of 19 and 39 years, pregnancy, leiomyomas, polyps, PCOS, and use of hormonal contraception are common causes of AUB.[34] In women 40 years and older, AUB may again be a symptom of the normal physiology of menopause but can also be a symptom of endometrial hyperplasia, leiomyomas, or endometrial carcinoma.[34]

A Newer Lexicon for Abnormal Uterine Bleeding

Many terms have been used to define menstrual irregularities. The lack of a common nomenclature has hindered research and development of evidence-based treatments. In 2011, the International Federation of Gynecology and Obstetrics (FIGO) proposed a system, PALM-COEIN,[3-6,35-38] that recommended replacing the term “dysfunctional uterine bleeding” (DUB) with “abnormal uterine bleeding” (AUB), and then adding a suffix to identify the proposed etiology. The PALM-COEIN nomenclature uses a classification system of structural and nonstructural causes followed by specific etiologies.[3-6] This terminology standardized the nomenclature and parameters for both normal uterine bleeding and AUB that occurs in reproductive age women, based on the 5th–95th percentiles identified in large epidemiologic studies.[4,6] The PALM-COEIN nomenclature has been adopted as the standard and outdated terms such as menorrhagia are no longer recommended to be used.[39,40] The widespread use of more precise language ultimately may facilitate both diagnostic efforts and health education/communication with women. **Table 11-6** summarizes the PALM-COEIN system.

Abnormal Menstrual Bleeding Assessment Framework: PALM-COEIN

Table 11-6

Terminology	Abbreviation	Description
PALM: Discrete Structural Entities Measurable Using Imaging Techniques and/or with Histopathology		
Polyp	AUB-P	Endometrial or endocervical polyps Categorized as present or absent, with no distinction regarding size or number
Adenomyosis	AUB-A	Disorder in which the ectopic endometrial tissue (endometrial glands and stroma) are present in the uterine myometrium. This causes uterine myometrial hypertrophy and hyperplasia. Clinical presentation is heavy menstrual bleeding and dysmenorrhea Adenomyosis is diagnosed via ultrasound or MRI. Subcategories based on diffuse vs focal or multifocal disease and volume have been proposed
Leiomyoma	AUB-L	Leiomyomatas (uterine fibroids) are fibromuscular tumors of the myometrium. First subclassification: Present or absent Second subclassication: Submucosal (SM) or other (O). Submucosal are further categorized as 0 (pedunculated intracavity) or 1/2 based on if less than 50% intramural or more than 50%. SM fibroids contribute to AUB. Other types are 3 (contacts endometrium, 100% intramural), 4 (intramural), 5 (subserosal ≥ 50% intramural), 6 (subserosal < 50% intramural), 7 (subserosal pedunculated), and 8 (includes cervical or parasitic and other lesions not related to the myometrium). Third subclassification: Used for hybrid lesions that describes the endometrial relationship first and serosal relationship second, separated by a hyphen
Malignancy and hyperplasia	AUB-M	Endometrial intraepithelial neoplasia (atypical hyperplasia) and/or malignancy. Subclassified by separate WHO and FIGO systems that stage malignancy based on histopathology and extent of the tumor.
COEI: Entities Not Defined by Imaging or Histopathology		
Coagulopathy	AUB-C	AUB secondary to a coagulopathy or systemic disorder that causes a coagulopathy. Approximately 13% of women with heavy menstrual bleeding have von Willebrand disease.
Ovulatory dysfunction	AUB-O	Disorders of ovulation can cause a spectrum of menstrual abnormalities that range from amenorrhea to heavy menstrual bleeding. Examples include PCOS, hypothyroidism, hyperprolactinemia, anorexia, extreme stress, gonadal steroids, and tricyclic antidepressants. Otherwise unexplained ovulatory dysfunction can occur during adolescence and the menopause transition.
Endometrial	AUB-E	AUB occuring within predictable and cyclic menstrual cycle, such as prolonged bleeding. This indicates ovulation is occuring. If no other etiology is identified, the primary disorder is likely to be in the endometrium.
COEI: Entities Not Defined by Imaging or Histopathology		
		The etiology may be infection, or a combination of mechanisms that interfere with local production of vasoconstrictors (e.g., prostaglandin F), increased production of hormones that break down endometrial clot (e.g., plasminogen activator) and/or increased production of substances that promote vasodilation (e.g. prostacyclin).
Iatrogenic	AUB-I	Many medical devices and medications can cause or contribute to AUB. Examples include intrauterine devices and warfarin (Coumadin). The AUB associated with estrogen and progestogen formulations administered continuously to induce amenorrhea is termed “break through bleeding.”
Not Otherwise Classified		

Not otherwise classified AUB-N	Causes of AUB that are rare or their role in causing AUB is not well defined. Examples include arteriovenous malformations and cesarean scar defects.

Abbreviations: AUB, abnormal uterine bleeding; FIGO, International Organization of Gynecology and Obstetrics; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; WHO, World Health Association.

Based on Munro MG, Critchley HO, Broder MS, Fraser IS. The FIGO classification system (PALM-COEIN) for causes of abnormal uterine bleeding in the non-gravid reproductive years including guidelines for clinical investigation. *Int J Gynaecol Obstet.* 2011;113:3-13.[6]

Evaluation of Abnormal Uterine Bleeding

The initial steps in evaluating a woman of reproductive age who has AUB are listed in **Table 11-7**. Medications associated with AUB are listed in **Table 11-8**. Because the list of differential diagnoses is extensive, the initial steps in the evaluation to assess for common etiologies of AUB first takes into consideration the following three primary factors: (1) the woman's age (i.e., proximity to menarche or menopause), (2) whether the AUB pattern is indicative of ovulatory or anovulatory status, and (3) the woman's a priori risk for endometrial cancer.

Table 11-7	Initial Evaluation of a Reproductive-Age Woman with Abnormal Uterine Bleeding

A. Initial History and Assessment

1. Determine if the bleeding is acute or chronic. Individuals who have acute vaginal bleeding or are hemodynamically unstable should be immediately referred for emergent care.
2. If chronic, establish the clinical impact that AUB has on activities of life.

   Assess for iron deficiency and symptoms of anemia
3. Assess for pregnancy: Pregnancy-related bleeding may present as any degree of bleeding, from light spotting to menstrual-like flow. The latter underscores the importance of considering pregnancy for all reproductive-age women who present with AUB.
4. Review health history using the PALM-COEIN system to focus on possible etiologies.

   Menstrual history:

   Age of menarche and menopause

   Detailed history of frequency, duration, predictability, amount of bleeding, interval, relation of AUB to normal menstrual cycle, associated symptoms.

   Sexual and reproductive history: Assess use of contraception, STIs, infertility, possible pregnancy.

   Symptoms associated with a systemic cause of AUB such as obesity, PCOS, hypothyroidism, hyperprolactinemia, or adrenal disorder

   Chronic medical illness that might cause a coagulopathy such as liver disease, renal disease, inherited bleeding disorders, systemic lupus erythematosus

   Medication history: Medications associated with AUB are listed in **Table 11-8**.

   Family history of bleeding disorders or women with "heavy periods," or thromboembolic disorders, or hormone sensitive cancers.

   Surgical history: Especially obstetric or gynecologic surgery

B. Physical Examination

A complete physical examination with attention focused on the following components:

Vital signs, BMI, blood pressure

Skin: The woman's skin should be assessed for signs of:

Coagulation disorder: pallor, bruising, bleeding gums, petechiae, swollen joints

Hyperandrogenism: hirsutism, acne, male-pattern baldness,

Insulin resistance: acanthosis nigricans on neck

Thyroid examination

Abdominal assessment for tenderness, distension, and palpable masses.

Gynecologic examination:

1. Origin of the bleeding: Bleeding that originates from the cervix, vagina, external genitalia, urinary tract, or rectum may appear different from uterine bleeding in volume, color, quality, and timing.
2. External genitalia should be examined for signs of trauma, lesions, hemorrhoids, or infection.
3. Speculum examination to identify sources of bleeding outside of the uterus such as cervical polyp, cervicitis, or vaginal laceration.
4. A bimanual pelvic examination to assess the uterus and adnexa for tenderness, size, and/or palpable masses.

C. Laboratory Tests

Initial laboratory testing for all types of AUB:

CBC with platelets

Ferritin or total iron and iron saturation

Pregnancy test

TSH

Transvaginal ultrasound to assess pelvic structures and endometrial thickness is usually included in a standard evaluation of reproductive-age women and postmenopausal women, but may not be necessary for adolescents near menarche.

Additional laboratory testing as indicated:

Endocrine disorders: FSH, LH, estradiol, progesterone level (obtained 22–24 days in menstrual cycle), free testosterone level, prolactin level,

Coagulation abnormalities: Coagulation profile, or von Willebrand diagnostic panel

STI: Chlamydia, wet mount of vaginal discharge, vaginal culture.

Cervical cancer screening

Additional tests as indicated:

Endometrial biopsy to evaluate the endometrium

Hysteroscopy

MRI

Abbreviations: AUB, abnormal uterine bleeding; BMI, body mass index; CBC, complete blood count; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; STI, sexually transmitted infection; TSH, thyroid-stimulating hormone.

Based on Munro MG, Critchley HO, Broder MS, Fraser IS. The FIGO classification system (PALM-COEIN) for causes of abnormal uterine bleeding in the non-gravid reproductive years including guidelines for clinical investigation. *Int J Gynaecol Obstet.* 2011;113:3-13[6]; American College of Obstetricians and Gynecologists. Committee Opinion No. 128: diagnosis of abnormal uterine bleeding in reproductive age women. Obstet Gynecol. 2012;120:197-206[34]; American College of Nurse-Midwives. Clinical Bulletin No. 15: abnormal uterine bleeding. *J Midwifery Womens Health*. 2016;61:522-527.[40]

Table 11-8 **Selected Drugs That Can Cause Abnormal Vaginal Bleeding**

Drug Category	Drugs: Generic (Brand)
Analgesics	Aspirin NSAIDs
Anticoagulants	Warfarin (Coumadin) Heparin
Anticonvulsant	Valproic acid (Depakene)
Antibiotics	Rifampin (Rifadin) Griseofulvin
Antidepressants	SSRIs[a]
Antiemetics	Metoclopramide (Reglan)[a] Prochlorperazine (Compazine)[a]
Antipsychotics	Phenothiazines (e.g., thioridazine [Mellaril], chlorpromazine [Thorazine], risperidone [Risperdal])[a] Tricyclics (e.g., amitriptyline [Elavil])[a]
Corticosteroids	Prednisone (Deltasone) Dexamethasone (Decadron)
Herbal supplements	Ginseng, ginkgo, motherwort
Hormonal contraceptives	Combined oral contraceptives: transdermal, vaginal, injectable Progestin-only pills Levonorgestrel-releasing intrauterine device
Menopausal hormone therapy	Estrogen, progesterone, androgens and combination formulations
Opioids	Methadone[a] Morphine[a]
Selective estrogen receptor modulators	Tamoxifen (Nolvadex)

Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

[a] Prolactin secretion from the pituitary is normally suppressed by dopamine. Any drug that blocks dopamine receptors can cause hyperprolactinemia which can then cause ovulatory dysfunction and AUB.

Based on Fritz MA, Speroff L. *Clinical Gynecologic Endocrinology and Infertility*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011[1]; Munro MG, Critchley HO, Broder MS, Fraser IS. The FIGO classification system (PALM-COEIN) for causes of abnormal uterine bleeding in the non-gravid reproductive years including guidelines for clinical investigation. *Int J Gynaecol Obstet*. 2011;113:3-13.[6]

For example, the physical examination for an adolescent will include assessment of sexual maturity and if the bleeding is heavy, signs of coagulopathy, but may not require a pelvic examination if she is not sexually active or just recently past menarche. The risk of endometrial cancer is quite low in adolescence, whereas etiologies discernable via laboratory evaluation are more likely. In contrast, a pelvic ultrasound and possibly endometrial biopsy is always considered for postmenopausal women in order to rule out malignancy, which is much more likely as women age.

The choice of imaging studies or endometrial biopsy in the evaluation of AUB is also an example of how the evaluation of AUB differs on the basis of age, type of bleeding, and risk

for endometrial cancer. Approximately 70% to 90% of women who develop endometrial cancer will have AUB. Risk factors for endometrial cancer that indicate a need for evaluation of the endometrium are listed in **Table 11-9**.[35] Evidence of an endometrial stripe larger than 4.0 mm on ultrasound suggests the possibility of endometrial hyperplasia or carcinoma, and is an indication for further investigation such as endometrial biopsy and possible surgical treatment such as endometrial curettage.[34,35,37] Endometrial biopsy is an office procedure that can be performed by midwives who have received training in the technique. The procedure is reviewed in **Appendix 11A**.

Table 11-9 **Risk Factors for Endometrial Cancer That Require Evaluation of the Endometrium**[a]

Age	Indication for Evaluation of the Endometrium
Postmenopausal	Any bleeding, staining, or spotting
45 years to menopause	Any AUB including intermenstrual bleeding, heavy menstrual bleeding, prolonged bleeding
19–45 years	Prolonged period of amenorrhea
	Any AUB in women with conditions associated with unopposed estrogen exposure such as obesity (BMI ≥ 30 kg/m^2)
	AUB that is persistent in women who are not obese but have one of the following:
	Chronic anovulation
	Failed medical management of bleeding
	Lynch syndrome

Abbreviations: AUB, abnormal uterine bleeding; BMI, body mass index.

[a] Additional risk factors not related to AUB include abnormal cervical cytology results, monitoring of women with endocervical hyperplasia.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 136: management of abnormal uterine bleeding associated with ovulatory dysfunction. *Obstet Gynecol*. 2013;122:176-185. [Reaffirmed 2016].[35]

Trauma and subsequent bleeding from genital lacerations is one of the differential diagnoses for women who present with AUB. Intimate-partner violence or sexual assault requires a more extensive assessment, and should involve consultation or referral to a community center or a professional experienced in working with individuals who have experienced assault or abuse (e.g., a rape crisis center or a sexual assault nurse examiner [SANE]).[41] Depending on the local laws that govern such cases, the midwife may also be legally required to report suspicion, or confirmation, of abuse. Most importantly, the midwife should initiate safety and support mechanisms. Referral to a surgeon may be necessary if anatomic damage is identified that appears to require surgery or extensive treatment.

Management of Women with Abnormal Uterine Bleeding

After normal menstrual changes, pregnancy, infection, trauma, and malignancy have been ruled out, interventions for AUB will vary based on the following initial considerations:

- Specific etiology
- Bleeding severity
- Associated symptoms such as pain or infertility
- Reproductive planning: desire for contraception and plans for pregnancy
- Medical comorbidities
- The woman's preferences with consideration of side effects of possible treatments

Furthermore, effective treatments can be either surgical or medical. For example, infection can be treated with antibiotics and leiomyomata can be treated with hormonal contraceptives or surgical resection. Therefore, when offering treatment for AUB, the woman's age, desire for pregnancy, and degree of bleeding factor into the management plan. Women with heavy menstrual bleeding secondary to leiomyomata who want to become pregnant may choose surgical therapy to preserve fertility whereas those who do not want to become pregnant can treat this condition with contraceptives that decrease menstrual bleeding.

In general, indications for treatment of AUB include heavy menstrual bleeding and AUB with ovulatory dysfunction (AUB-O). Women who are anemic should start iron supplementation regardless of the type of bleeding.

Heavy Menstrual Bleeding

Heavy menstrual bleeding (HMB) is defined as excessive bleeding, either in amount or in duration, at the regular interval of normal menstruation and by definition, presumes the woman is ovulatory. HMB should be treated if it is interfering with the woman's quality of life or when it causes anemia. The most common etiologies of HMB in reproductive age women are leiomyomatas and adenomyosis. The goal of treatment is to reduce the volume of menstrual flow, correct anemia, and prevent cancer.

The first line therapies for women with heavy menstrual bleeding are monophasic low-dose combined oral contraceptives or levonorgestrel-releasing intrauterine device (LNG-IUD).[33,37,40,42] Combined oral contraceptives have been shown to reduce menstrual blood loss by 35% to 69%.[43]

The choice between combined oral contraceptives and the LNG-IUD is based on the woman's desire for contraception, the presence, or absence of contraindications to estrogens, and personal preference. The combined oral contraceptives will induce a regular withdrawal bleed while the LNG-IUD is associated with irregular bleeding in the first months and then progress to amenorrhea.

While the typical treatment algorithm calls for combined oral contraceptives to be prescribed in the same manner as for women using the pills for contraception, evidence suggests that extended or continuous usage may be a more effective approach for treating heavy menstrual bleeding. This approach facilitates the stabilization of the endometrium and offers a

brief respite from the previously experienced excessive bleeding.[1] Injection of depot medroxyprogesterone acetate (DMPA) is also effective. The progesterone formulations are associated with irregular bleeding; headaches and weight gain in some women but ultimately these agents will result in amenorrhea. Amenorrhea, or menstrual suppression can be a lifestyle benefit as well as therapeutic value for some individuals, especially transmen. Additional information about menstrual suppression can be found in the *Hormonal Contraception* chapter.

If combined oral contraceptives, the LNG-IUD, or DMPA are not acceptable or are contraindicated, physician consultation is generally recommended unless the midwife is working as part of a physician–midwife team wherein guidelines for use of other agents are available. Other effective treatments for heavy menstrual bleeding include progesterone, GnRH agonists, nonsteroidal anti-inflammatory drugs (NSAIDs), danazol (Danocrine), a synthetic steroid that suppresses HPO axis activity and tranexamic acid (Lysteda). Progestin-only contraceptives and hormonal contraceptive inserts are not effective for treating heavy menstrual bleeding. However, orally administered progesterone in higher doses can be effective if used continuously for 21 days.

GnRH agonists (e.g., leuprolide [Lupron]) affect the HPO axis, hindering the ability of the ovaries to release the hormones required for normal function of the menstrual cycle. Interfering with cyclic menstruation causes the woman to enter a physiologic state resembling menopause. However, because of the bone mass loss associated with the decrease in estrogen levels and vasomotor menopausal symptoms, use of these medications tends to be limited to persons for whom other therapies have been unsuccessful, and may be best managed by a practitioner specializing in gynecologic disorders.[1] Prolonged treatment using GnRH agonists requires bone density monitoring.

Reduction in heavy menstrual bleeding occurs in women who are taking NSAIDs, due to the ability of these medications to block the synthesis of prostaglandins necessary for cyclic endometrial sloughing.[1] However, NSAID therapy is not always effective and can cause gastrointestinal bleeding with long-term use and for others, NSAID use can result in increased vaginal bleeding due to inhibition of platelet aggregation and prolongation of bleeding time. When using combined oral contraceptives, a woman also may take NSAIDs at the time of menstruation, and benefit from the combination of these medications.

Danazol (Danocrine), a synthetic steroid, has been successful in controlling heavy menstrual bleeding in some women, although it requires daily dosage for 3 to 6 months, given as 100 mg orally twice a day, during which time a state of amenorrhea is likely to occur. Significant androgenic side effects, including weight gain, acne, and seborrhea, are common with this medication, and the availability of other treatments has resulted in danazol no longer being the first choice of treatment for HMB.

Complementary/Alternative Treatments

While some observational studies have findings that support the treatment of women with HMB with traditional Chinese medicines and acupuncture, as well as with the use of herbal, homeopathic, and aromatherapy remedies, there is insufficient evidence to support use of

nonpharmacologic methods at this time.

Treatment for Abnormal Uterine Bleeding-Ovulatory Dysfunction

If AUB is not heavy menstrual bleeding but is suspected to be ovulatory dysfunction (AUB-O), the woman may present with irregular erratic bleeding that can vary from light to heavy. The underlying etiology is that lack of ovulation results in failure to produce a corpus luteum and the ovaries do not secrete progesterone. The lack of progesterone affects the uterine endometrium so that it continues to proliferate without the progesterone withdrawal induced shedding. Thus, the bleeding is irregular in timing and amount. After malignancy has been ruled out, the choice of treatment with progestin, estrogen, or a combination of the two has historically depended on the type of bleeding with which the woman presents. In general, infrequent menses has been treated first with progestin, while irregular bleeding has been treated initially with estrogen.[1] However, combination hormonal contraceptives are effective in controlling a number of menstrual disorders. Thus, many clinicians use combined oral contraceptives or another combined hormonal method as the first line of treatment, especially if the woman is interested in, or has no objection to the use of, contraception. With each monthly withdrawal cycle while on the combined hormonal methods, bleeding and cramping should decrease.

Dysmenorrhea

Painful menstruation, particularly in the lower abdomen and back and usually of a cramping nature, is known as *dysmenorrhea*. Dysmenorrhea usually is associated with regular, predictable menses. In the United States, this condition is experienced by 60% to 91% of menstruating adolescents and women.[1] Dysmenorrhea that occurs in the absence of other disease is termed *primary dysmenorrhea*. Dysmenorrhea that is caused by a disorder such as endometriosis or leiomyomata is termed *secondary dysmenorrhe*a.

In distinguishing dysmenorrhea from other causes of pelvic pain, it is important to establish this pain as cyclic in nature, coinciding with the onset of menses and resolving after cessation of the menstrual flow. Primary dysmenorrhea is typically recurrent, crampy, and may radiate to the back or thighs. It can be accompanied by nausea, fatigue, and general malaise. Primary dysmenorrhea generally starts just before the onset of menses and lasts 2 or 3 days.

The principal cause of primary dysmenorrhea is the presence of prostaglandins that are released from the endometrium at the beginning of menses. These prostaglandins induce uterine contractions which result in uterine ischemia and accumulation of metabolites that stimulate pain nerves (**Figure 11-2**).[44,45] Primary dysmenorrhea usually begins in adolescence after ovulatory cycles are established. Pain can be mild to severe and generally improves as the woman ages.

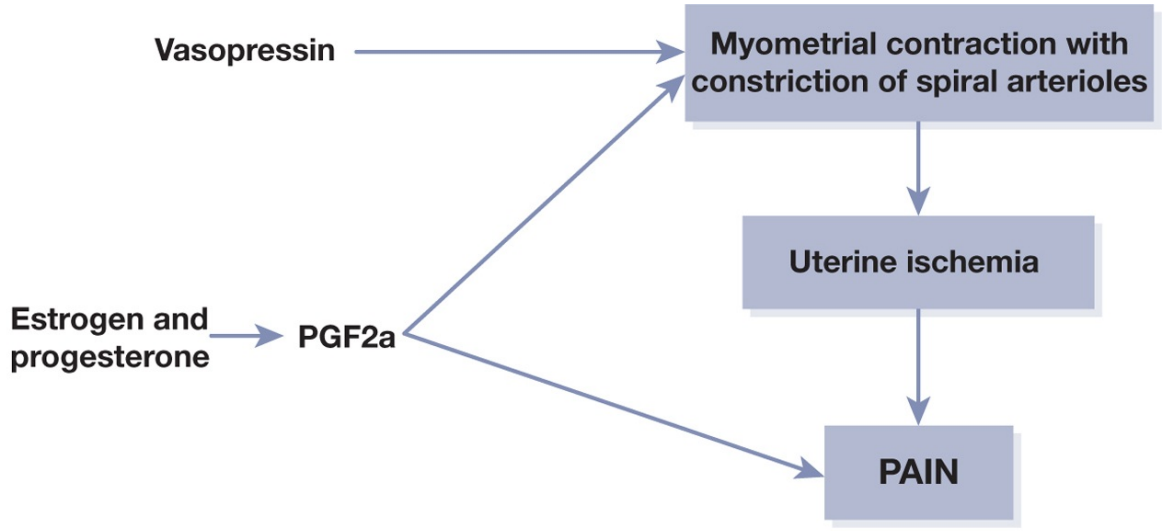

Figure 11-2 Pathophysiology of primary dysmenorrhea.

Evaluation of an Individual with Dysmenorrhea

The evaluation of women with dysmenorrhea focuses on excluding the presence of disorders

that can cause cramping uterine pain.[46] Although endometriosis is the most common cause of secondary dysmenorrhea, other etiologies include pregnancy, an IUD in place, pelvic inflammatory disease, adenomyosis, ovarian cysts, pelvic adhesions, or cervical stenosis. Nongynecologic causes include inflammatory bowel disease and irritable bowel syndrome.

Treatment of an Individual with Primary Dysmenorrhea

The goal of treatment for women with primary dysmenorrhea is to relieve pain. Application of local heat to the abdomen has demonstrated effectiveness that in some women is equal to the relief achieved after taking ibuprofen (Advil).[47] The first line pharmacologic agents recommended are NSAIDs because these drugs inhibit prostaglandin synthesis.[46] There is no one NSAID that is more effective than others so the choice of agent depends on individual choice and tolerability as these drugs are associated with some adverse effects. The medications should be taken for 2 to 3 days beginning on the first day of symptoms on a fixed schedule to maximize effectiveness.

The primary adverse effect of NSAIDs in healthy women is gastrointestinal distress, but these agents are also (albeit less frequently) associated with peptic ulcer, renal injury, hepatotoxicity, and bronchospasm in persons with asthma. Furthermore, these induce several drug–drug interactions. Therefore, before prescribing an NSAID that will be taken on a regular basis, a review of the woman's health and current medications is needed. Although acetylsalicylic acid (aspirin), another NSAID, has also been found to offer some relief from dysmenorrhea, there is no evidence that the non-NSAID analgesic acetaminophen (Tylenol) is beneficial in eliminating menstrual pain.[47]

If dysmenorrhea persists, consideration of alternative therapies may become necessary. Because combined hormonal contraceptives decrease prostaglandin synthesis and menstrual flow, these drugs are frequently used on an off-label basis for the treatment of women with dysmenorrhea.[48] In addition, the various progestin-only methods of contraception (injectable DMPA, progestin-only oral contraceptives, levonorgestrel-containing IUDs, and etonogestrel-containing implants) often result in temporary states of amenorrhea due to decreased endometrial stimulation. In turn, these methods can result in less dysmenorrhea.[49]

Several nonpharmaceutical approaches to the treatment of women with dysmenorrhea have been widely advocated. Among them are the application of local heat in the form of small heat packs continuously applied to the abdomen, homeopathy (e.g., belladonna and chamomilla), acupuncture, biofeedback, dietary supplements, relaxation techniques, massage, exercise, aromatherapy (e.g., rose oil), and the use of certain herbs (e.g., black cohosh, raspberry leaf, shakuyaku-kanzo-to, semen coicis, and chaste berry).[50-56] With the exception of the use of local heat application, there is limited scientific evidence of effectiveness for the various nonpharmaceutical modalities.

Conclusion

Menstrual cycle abnormalities are a common reason for seeking healthcare services and assessment requires a sensitive and thorough approach. Exploring the individual's sense of reproductive or hormonal well-being or normalcy can often be achieved by taking a comprehensive history of the menstrual pattern and examining attitudes and beliefs about the significance of, and even need for, cyclic bleeding. Treatment of menstrual abnormalities can positively influence a person's long-term health well beyond the specific change appreciated by the person at the outset of care. This aspect of health care calls upon midwives' expertise as primary and gynecologic care clinicians who are concerned with the entirety of women's health.

Endometrial Biopsy

WENDY GRUBE AND WILLIAM F. McCOOL

© hakkiarslan/iStock/Getty Images Plus/Getty

Endometrial biopsy (EMB) using a flexible plastic device is a cost-effective, safe, and simple method of collecting a histologic sample of the uterine endometrium. A number of clinical circumstances can require investigation of the endometrium, especially among women who experience abnormal uterine bleeding (AUB) that might be associated with premalignant hyperplasia or carcinoma. The risk of uterine perforation associated with EMB is less than the risk of uterine perforation associated with dilatation and curettage (D & C) (0.1–0.2%, versus 0.3–2.6%, respectively.)[1] The diagnostic D & C is no longer considered the "gold standard" for this purpose due to surgical risks, need for anesthesia, and cost.[1,2] The evolution of sampling devices such as the Pipelle has allowed EMB to be easily accomplished in an office setting by providers.

The sensitivity and specificity of EMB have been noted to be 100% for detection of endometrial carcinoma, hyperplasia, proliferative and secretory endometrium.[2] Sensitivity for detection of endometritis has been estimated at 88.9%, and sensitivity for detection of endometrial polyps has been estimated at 60%.[2] This limitation is primarily due to the limited surface area of the uterine lining that is capable of being sampled via EMB devices. Combining transvaginal ultrasonography and sonohysterography with EMB can assist with the identification of such structural abnormalities as well as location of focal pathology.

Indications

1. Postmenopausal women with any uterine bleeding
2. AUB in women older than 45 years, or women at any age if AUB has not been controlled with appropriate medications
3. Examination of thickened endometrium (> 4 mm) noted on transvaginal ultrasound of the uterus in the sagittal position to rule out endometrial cancer or precursors
4. Evaluation of atypical glandular cells (endometrial or other) found in cervical cytology

sampling
5. Women at high risk for endometrial cancer, such as those on tamoxifen therapy, a history of Lynch syndrome therapy, a history of Lynch syndrome, and women who have undergone treatment for endometrial cancer with uterus-sparing therapy
6. Assessment of adverse pregnancy outcomes that may be secondary to chronic subclinical endometritis

Contraindications

1. Viable and desired pregnancy
2. Known or suspected cervical cancer
3. Clotting disorder
4. Inability to visualize cervical os
5. Obstructing cervical lesion

Relative Contraindications Requiring Consultation

1. Infection of the vagina, cervix, or uterus requires evaluation and treatment prior to EMB procedure
2. Use of medications that may alter clotting requires consultation with a provider who is knowledgeable in hematologic disorders
3. History of prosthetic heart valve requires cardiologist consultation, and antibiotic prophylaxis
4. Fever (temperature > 38°C [100.4°F]) at the time of the procedure
5. Severe cervical stenosis or atypical uterine anatomy requires consultation with or referral to a gynecologist

Potential Side Effects/Complications and Preventive Measures

1. Cramping, uterine spasm, and vasovagal response are the most common side effects associated with this procedure. Prophylactic analgesia with 600–800 mg ibuprofen (Advil) administered 60 minutes prior to the procedure is recommended. In addition, women should be encouraged to eat prior to the procedure to avoid symptoms of hypoglycemia.
2. Uterine perforation. The following decrease the risk of uterine perforation:
   a. Make certain that the woman is not pregnant or has a well-involuted postpartum uterus
   b. Perform a thorough pelvic examination prior to the procedure to note the uterine and

cervical size, position, and angulation, as well as any structural abnormalities

c. Use a tenaculum to straighten the utero-cervical angle if the uterus is not close to axial in position.

3. Uterine infection, pelvic infection, and bacteremia.
4. Excessive uterine bleeding is rare but may occur if the woman has an undiagnosed coagulopathy.

Procedure

1. If the purpose of the sample is confirmation of ovulation/diagnosis of luteal-phase defects, schedule the procedure for day 22 or 23 of the menstrual cycle. Timing is not important if the sampling is being performed to detect cancer or its precursors.
2. Gather equipment needed for the procedure:[1-3]
   a. Informed consent form
   b. Nonsterile and sterile gloves
   c. Vaginal speculum of appropriate size
   d. Ring forceps and cotton balls or large cotton swabs
   e. Antiseptic solution (such as Betadine or Hibiclens)
   f. Topical anesthetic such as Benzocaine gel 20% (Hurricaine) or 2% lidocaine
   g. Scissors
   h. Labeled specimen containers with 10% formalin
   i. Endometrial sampling devices (make certain there are at least two available)
   j. Tenaculum

A sample tray for endometrial biopsy is shown in **Figure 11A-1**.

Figure 11A-1 Sample tray for endometrial biopsy.

3. Thoroughly review the woman's health history, including the date of last menses, contraception and possibility of pregnancy, risk of sexually transmitted infection, known bleeding disorder, medication or supplement use, and allergies. Based on this information, contraindications may emerge that preclude performance of the procedure, or additional testing prior to the EMB may be necessary such as a pregnancy test, STI diagnostic testing, saline or potassium hydroxide (KOH) slide tests, or complete blood count.
4. Provide education and instruction regarding the procedure, side effects, and possible adverse effects of EMB. Informed consent must be obtained before proceeding.
5. Offer an NSAID oral agent to decrease cramping and uterine spasm associated with the procedure.
6. Assist the woman to assume a lithotomy position. Using nonsterile gloves, perform a bimanual and rectovaginal examination (if needed) to verify uterine and cervical position, angle, and structure to ensure that the curette can be placed in the appropriate direction and to minimize the risk of uterine perforation.
7. Insert the appropriately sized speculum.
8. Apply antiseptic solution to the cervix with a large cotton swab or cotton ball.
9. If desired, apply topical anesthetic (e.g., Benzo-caine gel 20%) to the anterior lip of the cervix and into the os with a small cotton swab to lessen the pain associated with the curette or tenaculum. If additional pain reduction is indicated, 5 mL of 2% lidocaine can be instilled into the endometrial cavity through a small catheter.[1]

10. If a tenaculum is needed, place the tenaculum on the anterior lip of the cervix, and gently pull the device to straighten the utero-cervical angle. An assistant can be asked to hold the tenaculum and thereby maintain this angle.
11. Change to sterile gloves, remove the curette (the outer sheath and inner piston) from the sterile package as instructed on the package insert.
12. With the piston fully inserted into the sheath, gently introduce the curette through the cervical os and into the uterine cavity until resistance is felt (**Figure 11A-2).** If strong resistance is encountered prior to reaching the fundus, stop the procedure.
13. If there is difficulty advancing the device through the inner os, the introduction of a small cervical dilator or a uterine sound by using steady, moderate pressure may be helpful. Another option is to discontinue the procedure and insert a 3-mm osmotic laminaria, which can be placed in the cervix on the morning of the day of the EMB and removed that afternoon prior to conducting the actual procedure.
14. Once resistance is felt, note the distance that the curette has entered the uterus, using the markings located on the sheath. On average, the length of the cervix from external to internal os is 2.5 cm, and the total distance from the external os to the wall of the fundus is approximately 6 to 9 cm. This information should be noted and recorded in the woman's health record.
15. With the tip of the device at the fundus, hold the curette securely, and slowly but consistently partially withdraw the inner piston. Withdrawal of the piston creates the suction, or negative pressure, at the tip needed to collect the tissue sample. It is not necessary to withdraw and replace the piston repeatedly; indeed, doing so is counterproductive. The piston should *not* be totally withdrawn or suction will be lost.
16. Move the sheath of the device back and forth, with the tip moving from fundus to internal os, while simultaneously rolling it between the thumb and fingers to allow collection of cells from different levels of the endometrium as well as different locations. Avoid allowing the tip of the device to slip back out of the internal os into the cervical canal, as this will result in the loss of suction.
17. Complete the simultaneous moving and rolling of the sheath maneuver until the sheath is filled. Both tissue and some blood should be visible.
18. Remove the device. If only blood can be visibly identified within the sheath, after removing the entire curette, place the contents in formalin, and use another curette to attempt the procedure once or twice more depending on the woman's consent and how well the procedure is tolerated. The same curette can be reused if it has maintained sterility, including not touching the formalin.
19. Once the tissue has been adequately collected, cut the distal tip from the device and place the tip in the labeled formalin container. Cutting the tip from the device allows the sample to be removed intact, without causing the cell breakup that can occur when tissue is forced through the tip. Placing the tip of the catheter in the specimen container ensures that any tissue collected in this portion of the device will be analyzed with the remainder of the specimen.
20. Gently press the piston back into the sheath to expel the remaining specimen into the same labeled container.

21. Remove the tenaculum and speculum, but encourage the woman to remain supine for a few minutes prior to getting up and dressed to reduce the risk of a vasovagal response. It is common for a woman to experience some cramping either during the procedure or immediately afterward; anticipatory guidance is indicated on this possibility.
22. Instruct the woman to expect some light spotting during the next few days, but to contact the office if bright red blood or excessive bleeding or clotting, fever, vaginal discharge with a foul odor, pelvic cramping, or pain occurs. Counseling includes advising no vaginal penetration sexual intercourse for 2 to 3 days after the procedure.
23. Document the procedure, including any analgesic or anesthetic given, any abnormal findings during examination or procedure, the sampling device used, the depth of insertion of the curette, adequacy of the specimen obtained, and the woman's toleration of the procedure.

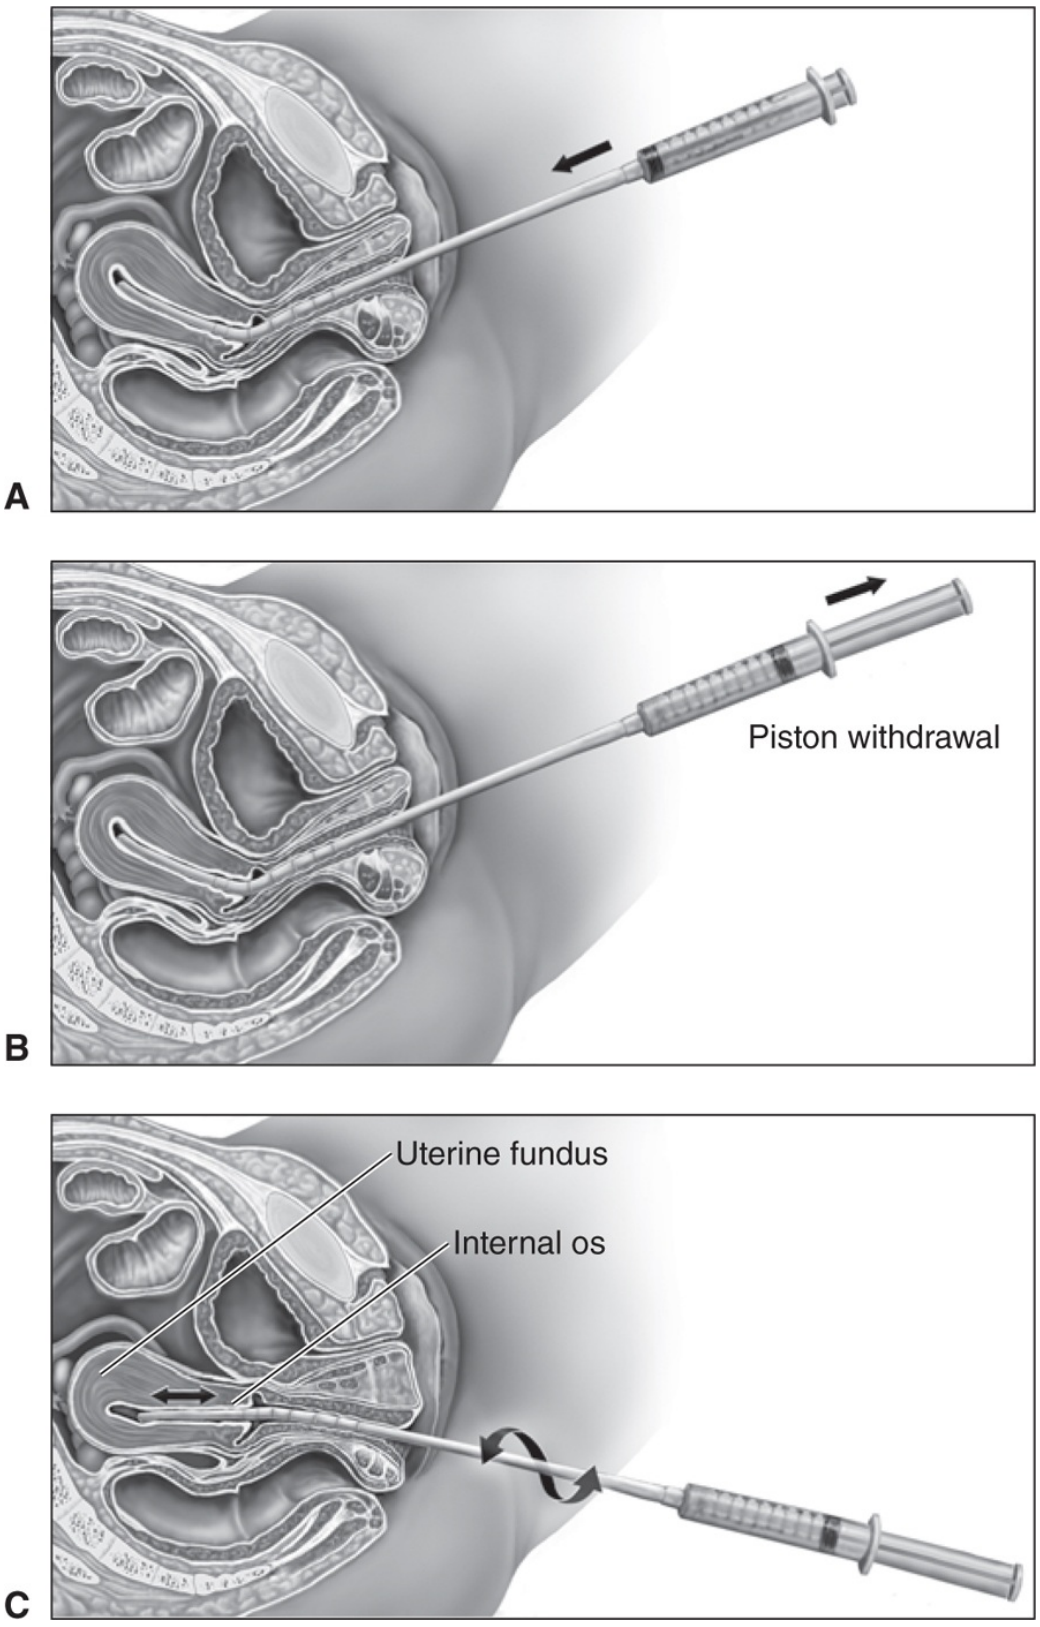

Figure 11A-2 Endometrial biopsy technique. **A.** Insert the device until resistance is felt or the uterine fundus is reached (Step 12). **B.** Withdraw the piston from the fully inserted device (Step 15). **C.** Rotate the device through 360 degrees while moving it back and forth between the fundus and the internal cervical os.

Results and Management

Laboratory findings can vary in language and presentation depending on the laboratory reporting system. In general, the provider will receive a histology report, with information that can contribute to making a diagnosis regarding the status of the endometrium. In communicating the findings to the woman, the provider should ensure that the woman understands the results and the possible courses of action to follow. The most common histologic reports received, with suggestions for follow-up, are listed in **Table 11A-1**.

Table 11A-1 Common Histologic Findings from Endometrial Biopsy Samples

Histology	Probable Diagnosis	Suggested Management	Need for Referral
Insufficient cells or unable to assess	Unable to assess	Dependent on clinical indication for EMB; may repeat EMB or potential referral for dilatation and curettage	Dependent upon specific clinical indication
Inactive endometrium	Hypoestrogenic state	Dependent on clinical presentation and indication for EMB	Dependent upon specific clinical indication
Proliferative (estrogen-influenced preovulation), disorganized proliferative endometrium or secretory (progesterone-influenced postovulation)	AUB	TVUS to rule out structural pathology Hormonal therapy such as combined oral contraceptives, or cycling with progestins or a LNG-IUS if the woman is of reproductive age	Women with an abnormal TVUS, or those who do not respond to hormonal therapies as expected
Simple or complex nonatypical hyperplasia	Premenopausal or perimenopausal woman	Combined oral contraceptives, cycling with progestins, or insertion of a LNG-IUS Repeat EMB in 6 months	No response to hormonal therapy
	Postmenopausal woman	No therapy, or hormonal therapy depending on amount of bleeding, age, and time lapsed from menopause (discussed in more detail in the *Midlife, Menopause, and Beyond* chapter)	Continued irregular bleeding, or no response to hormonal therapy
Atypical hyperplasia (simple or complex)—suspicion of cancer	Rule out endometrial carcinoma	Refer to a specialist (e.g., collaborating physician or gynecologic oncologist) for probable surgery	Continued irregular bleeding, or no response to hormonal therapy

Abbreviations: AUB, abnormal uterine bleeding; EMB, endometrial biopsy, LNG-IUS, levonorgestrel intrauterine system; TVUS, transvaginal ultrasound.

Introduction

Often members of the public envision midwives exclusively as providers of maternity care. That perception is false—and has been for many years.[1] Even in past millennia, midwives were known as healers of their communities and cared for women, and sometimes men, with a variety of ailments. Maternity care and gynecologic care frequently overlap, as may occur during the care of a woman who has an abnormal Pap test during pregnancy. Surveys of certified nurse-midwives (CNMs) and certified midwives (CMs) have found that almost 70% of those in clinical practice offer healthcare services to nonpregnant women.[2]

The word *gynecology* originates from the Greek language and means "the study of women." Although it usually is defined as health care focusing on diseases of women, gynecology today connotes care of nonpregnant women and centers on the maintenance of healthy reproductive organs and the treatment of women with various conditions that may negatively affect the reproductive system. This does not imply that care focuses only on issues of childbearing functions of the reproductive system, as not all women plan to become pregnant.

The organs most closely associated with gynecologic health traditionally include the breast, cervix, endometrium/uterus, ovaries, vulva, and vagina. This chapter provides an overview of common gynecologic conditions that biological females experience throughout their lifetime, and the information needed to screen for gynecologic cancers. Because cervical cancer screening is one of the most frequent services performed by midwives, it is discussed first and in detail. Gynecologic conditions such as pelvic pain, pelvic masses, and other disorders of reproductive organs are reviewed as well. Lastly, multiple-organ conditions such as infertility and sexual disorders are addressed. Although breast conditions are usually considered part of gynecology, they are discussed in detail in the *Breast Conditions* chapter.

Among the most important skills of any midwife is the ability to individualize care, particularly based on a person's culture, gender identity, age, physical/mental characteristics, and risk factors for disease. Recognition of personal beliefs and having the ability to overcome implicit biases are necessary to provide person-centered care.[3,4]

Historically, the annual gynecologic examination has often been for the purpose of obtaining an annual Pap test. However, professional organizations such as the U.S. Preventive Services Task Force have found there is inadequate evidence supporting regular pelvic examinations for asymptomatic women.[5] Today, the conversation has shifted away from the "routine annual Pap test" and toward individualized care and improvement of outcomes based on the individual's health needs. Furthermore, advancements in Pap test technology and greater acceptance of long-acting contraceptives mean that women of reproductive age do not always need an annual visit, although periodic visits for health screening remain cornerstones of preventive care.

Screening for Malignancies

Breast, lung, and colon cancer are the most common causes of cancer among women living in the United States, with lung cancer surpassing breast cancer as the leading cause of cancer death in women.[6] Among the malignancies commonly termed “gynecologic cancers,” only cervical cancer can be detected through regular screening of low-risk and at-risk women. Pap testing is one of the most common screening tests performed by midwives. However, screening for cervical cancer has become more complex over the last few years with regard to time of initiation, years of duration for routine screening, and interpretation of results.

Cancer of the Uterine Cervix

Since the 1980s, it has been well recognized that virtually all cases of cervical cancer are caused by infection with a high-risk type of human papillomavirus (HPV).[6] HPV is a small deoxyribonucleic acid (DNA) virus that is easily transmitted from one person to another via close skin-to-skin physical contact or unprotected penetrative intercourse. HPV enters the body through microscopic breaks in the skin and can be transmitted via any type of sexual stimulation.[7,8] While more than 150 genotypes of HPV have been identified, approximately 40 are known to infect the anogenital area. To date, 12 to 14 major HPV types have been linked to the development of cervical cancer, with types 16 and 18 responsible for approximately 70% of all cervical cancers.[9]

The ability to test for high-risk HPV types when using liquid-based Pap tests has changed cervical cancer screening practices. Cervical cancer can take years to develop, thus, population-based screening can be effective for identification of this cancer or precursor lesions. Testing for high-risk HPV types can be performed singly, as a co-test with a Pap test, or as "reflex" testing if the Pap test identifies abnormal cells.

Cervical Cancer Screening Tests

Since the introduction of liquid-based cytology and the advent of testing for high-risk HPV DNA, liquid-based testing has replaced glass-slide techniques in most developed nations. Today, more than 90% of laboratories use liquid-based Pap testing because this technology assures improved quality of the sample, improved reproducibility, fewer false negatives, and the ability to test for HPV.[10]

Pap Test

As described in the *Anatomy and Physiology of the Female Reproductive System* chapter, the external cervix (ectocervix) is covered with smooth, pink, squamous epithelial cells. The inner section of the cervical os is lined with columnar epithelial cells. The squamocolumnar junction is the site of active metaplasia, or conversion of one cell type (columnar epithelium) to another (squamous epithelium), although these changes are not grossly visible. The squamocolumnar junction is clinically important because the cells around it, called the *transformation zone*, tend to be the site of most abnormalities. For this reason, healthcare providers attempt to obtain cells from this area for a Pap test. When abnormalities occur in the cells within the *transformation zone*, they often are characterized by the term *dysplasia*—an umbrella term referring to abnormal cells that may signify a stage preceding the development of cancer.

In women who are pregnant or using hormonal contraception, the presence of pronounced eversion of the columnar epithelium, also known as *ectopy*, often enhances the possibility of obtaining satisfactory cells for a Pap test. Conversely, during late childhood and early adolescence, the squamocolumnar junction is deep inside the endocervix, and the cervix tends to appear only to have squamous cells. Similarly, women who are in the postmenopausal period may lack any visual appearance of the endocervix. Pap testing may be more challenging

for women in these subpopulations. The procedure for performing a Pap test is described in the *Collecting Urinary, Vaginal, Cervical, and Rectal Specimens for Testing and Interpretation of Saline and KOH Slides* appendix in the *Introduction to the Care of Women* chapter.

Human Papillomavirus DNA Test

In 2014, the U.S. Food and Drug Administration (FDA) approved the use of a specific brand of HPV DNA test (cobas) as a stand-alone screen for cervical cancer in women age 25 years and older. A large trial involving more than 42,000 women, conducted in the United States, demonstrated the effectiveness and sensitivity of HPV infection as a first-line screening test for cervical cancer, finding that it yielded fewer false-negative results when compared with Pap testing.[11] In 2015, the American Society for Colposcopy and Cervical Pathology endorsed use of HPV DNA testing for primary screening; an algorithm that provides guidance for clinicians using HPV-only testing for primary screening is also available.[12-14] When choosing HPV DNA testing for primary cervical cancer screening, it is essential that the referral laboratory use only the FDA-approved HPV test (cobas).

Cervical Cancer Screening Recommendations

Current age-based cervical cancer screening guidelines for all women, including those who have been either fully or partially vaccinated against HPV, are recommended as summarized in **Table 12-1**.[14-15] HPV vaccination does not negate the need for continued cervical cancer screening.

Table 12-1 Cervical Cancer Screening Guidelines for Women at Low Risk for Cervical Cancer[a]

Age and Characteristics	ACS, ASCCP, ASCP	USPSTF	ACOG
< 21 years	No screening	No screening	No screening
21–29 years[b]	Every 3 years: conventional cytology without HPV co-test	Every 3 years: conventional cytology without HPV co-test	Every 3 years: conventional cytology without HPV co-test
≥ 30–64 years	Every 3 years: conventional cytology *or* Every 5 years: with HPV co-test	Every 5 years: with HPV co-testing preferred *or* Every 3 years: conventional cytology	Every 5 years: conventional cytology with HPV co-testing preferred *or* Every 3 years: conventional cytology
≥ 65 years	No further screening if prior screening was negative and no other high-risk factor for cervical cancer exists	No further screening if prior screening was negative and no other high-risk factor for cervical cancer exists	No further screening if no abnormal tests in past 10 years
≥ 65 years with history of CIN II, CIN3, or AIS	Continue screening for 20 years after regression or management		Continue screening for 20 years after regression or management
After hysterectomy with removal of cervix	No screening unless positive history of high-grade precancerous lesion or cervical cancer	No screening unless positive history of high-grade precancerous lesion or cervical cancer	No screening unless positive history of high-grade precancerous lesion or cervical cancer
HPV-vaccinated	Regular age-specific screening	Regular age-specific screening	Regular age-specific screening

Abbreviations: ACOG, American College of Obstetricians and Gynecologists; ACS, American Cancer Society; AIS, adenocarcinoma in situ; ASCCP, American Society for Colposcopy and Cervical Pathology; ASCP, American Society for Clinical Pathology; CIN, cervical intraepithelial neoplasia; DES, diethylstilbestrol; HIV, human immunodeficiency virus; HPV, human papillomavirus; USPSTF, U.S. Preventive Services Task Force.

[a] These guidelines do not apply to women exposed in utero to DES, or those who have had a diagnosis of a high-grade precancerous cervical lesion, have a diagnosis of cervical cancer, are HIV-positive, or are immunosuppressed.

[b] Biological females 21 years or older who have never had sex are very low risk for developing cervical cancer, and screening in this population is dependent on individual clinician judgment.

Based on Saslow, D, Solomon D, Lawson, H, et al. American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology screening guidelines for the prevention and early detection of cervical cancer. *J Low Genit Tract Dis.* 2012;16:175-204[13]; American College of Obstetricians and Gynecologists. Practice Bulletin No. 168: cervical cancer screening and prevention. *Obstet Gynecol.* 2016;128:e111-e130[14]; Moyer V. Screening for cervical cancer: U.S. Preventive Services Task Force recommendation statement. *Ann Intern Med.* 2012;156:880-891.[15]

Professional organizations in the United States recommend against performing a Pap test for women younger than 21 years, unless the woman has a history of an immunosuppressed condition (e.g., human immunodeficiency virus [HIV] infection).[13-15] Most HPV types, including 16 and 18, resolve spontaneously in younger women and do not increase the risk of cervical cancer later in life unless HPV infection remains persistent over time. If testing occurs inadvertently for a woman younger than 21 years, and the result was either *atypical squamous cells of undetermined significance* (ASC-US) or low-grade squamous intraepithelial lesion (LSIL), a repeat cytology can be performed in 1 year. Alternatively, if the result of the original Pap test is high-grade squamous intraepithelial lesion (HSIL), then a colposcopy is warranted.[15-17]

For women between ages 21 and 29 years, Pap test alone is recommended every 3 years. HPV DNA testing is recommended only for women who have Pap test results showing ASC-US. For women 30 years or older, the recommendation is to perform either co-testing with cytology and HPV DNA testing every 5 years, or Pap test alone every 3 years.[13,14]

Cervical cancer screening is discontinued in women age 65 years or older unless they meet the criteria noted in **Table 12-1**. Women in this age group who have undergone a hysterectomy that included removal of the cervix and have no history of a past high-grade cervical lesion (cervical intraepithelial neoplasia [CIN] 2, 3, or greater) no longer need a Pap test.[13,14]

Interpretation of Cervical Cancer Screening Results

Interpretation of cytology findings, as reported by a properly accredited laboratory, follows the internationally accepted Bethesda Classification System of cervical cytological reporting, which was last updated in 2014 (**Table 12-2**).[18] This classification is based on *cytology*, rather than *histology*. Cytology is the study of function and structure of individual cells, such as cells found on a Pap test; by comparison, histology is the study of the microscopic structure of tissue specimens, belonging to a specific organ, usually obtained via a biopsy. The diagnosis and staging of cervical cancer findings are performed histologically, and necessitate testing beyond that involved in a Pap test—most often a biopsy obtained during a follow-up colposcopic examination or other operative procedure. For women with abnormal Pap test results, the information should be shared with sensitivity because, although cytology results are often revealed ultimately to be normal when a histologic examination is performed, such a result can be a source of anxiety for women.

Table 12-2	**The 2014 Bethesda System**
Specimen Type	
Indicate conventional smear (Pap smear) versus liquid-based preparation versus other	
Specimen Adequacy	
Satisfactory for evaluation (*describe presence or absence of endocervical/transformation zone component and any other quality indicators [e.g., partially obscuring blood, inflammation]*)	
Unsatisfactory for evaluation (*specify reason*)	
Specimen rejected/not processed (*specify reason*)	
Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (*specify reason*)	
General Categorization (*Optional*)	
Negative for intraepithelial lesion or malignancy	
Other: See Interpretation/Result (*e.g., endometrial cells in a woman ≥ 45 years*)	
Epithelial cell abnormality: See Interpretation/Result (*specify* “squamous” *or* “glandular” *as appropriate*)	
Interpretation/Result	
Negative for Intraepithelial Lesion or Malignancy (*When there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report—whether or not there are organisms or other non-neoplastic findings*)	

Non-Neoplastic Findings (Optional to Report)

Non-neoplastic cellular variations

- Squamous metaplasia
- Keratotic changes
- Tubal metaplasia
- Atrophy
- Pregnancy-associated changes

Reactive cellular changes associated with:

- Inflammation (includes typical repair)
- Lymphocytic (follicular) cervicitis
- Radiation
- Intrauterine contraceptive device (IUD)

Glandular cells status post hysterectomy

Interpretation/Result

Organisms

Trichomonas vaginalis

Fungal organisms morphologically consistent with *Candida* spp.

Shift in flora suggestive of bacterial vaginosis

Bacteria morphologically consistent with *Actinomyces* spp.

Cellular changes consistent with herpes simplex virus

Cellular changes consistent with cytomegalovirus

Other

Endometrial cells (*in a woman age ≥ 45 years*) (*Specify if "negative for squamous intraepithelial lesion"*)

Epithelial Cell Abnormalities

Squamous cell

Atypical squamous cells

- Of undetermined significance (ASC-US)
- Cannot exclude HSIL (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL) (*encompassing: HPV/mild dysplasia/CIN 1*)

High-grade squamous intraepithelial lesion (HSIL) (*encompassing: moderate and severe dysplasia, CIS; CIN 2 and CIN 3*)

- With features suspicious for invasion (*if invasion is suspected*)

Squamous cell carcinoma

Glandular cell

- Atypical
- Endocervical cells (not otherwise specified [NOS] *or specify in comments*)
- Endometrial cells (NOS *or specify in comments*)
- Glandular cells (NOS *or specify in comments*)

Atypical

- Endocervical cells, favor neoplastic
- Glandular cells, favor neoplastic

Endocervical adenocarcinoma in situ
Adenocarcinoma
Endocervical
Endometrial
Extrauterine
Not otherwise specified (NOS)
Other malignant neoplasms (specify)
Adjunctive Testing
Provide a brief description of the test method(s) and report the result so that it is easily understood by the clinician.
Computer-Assisted Interpretation of Cervical Cytology
If the specimen is examined by an automated device, specify the device and result.
Educational Notes and Comments Appended to Cytology Reports (*Optional*)
Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included).

Abbreviations: ASC-US, atypical squamous cells of undetermined significance; ASC-H, atypical squamous cells, cannot exclude a high-grade squamous intraepithelial lesion; CIN, cervical intraepithelial neoplasia; CIS, carcinoma in situ; HPV, human papillomavirus; spp, species.

Miscellaneous Organisms Identified on Pap Test

Pap testing is a screening test designed to detect cervical cancer. However, when reviewing specimens, cytologists and pathologists may note the presence of incidental organisms unrelated to cervical cancer, such as *Trichomonas*, *Candida*, coccobacilli, or the presence of endometrial cells. When *Trichomonas* is identified on a Pap result, this finding is not considered diagnostic for infection that requires treatment because false negatives and false positives are known to occur. In such a case, it is recommended that the midwife recall the woman for confirmatory testing by office-based examination of vaginal secretions via saline prep wet mount, or preferably via nucleic acid amplification testing (NAAT).[19]

Candida found on a Pap test does not necessarily require treatment either. *Candida* forms colonies intravaginally as a component of normal flora, and the presence of this organism on a Pap test report does not correlate well with the woman's clinical presentation. If she reports symptoms of vaginal candidiasis, signs of vulvovaginitis are present, fungal elements are confirmed on microscopic examination, and potassium hydroxide (KOH) testing is positive, then treatment is indicated.

Similarly, Pap tests may report cellular changes associated with the presence of herpes simplex virus (HSV). However, a Pap test is neither a screening nor a diagnostic test for herpes.[19] Obtaining an HSV culture of a visible lesion and testing by polymerase chain reaction (PCR) remain the most accurate methods of identifying herpes. In the asymptomatic woman, type-specific serology will determine the presence of antibodies (evidence of past exposure) to herpes but a positive serology result does not provide information about a current

outbreak or when the woman may have been exposed to herpes. The Centers for Disease Control and Prevention (CDC) recommends against routine serologic screening for herpes in the general population. If a Pap test result indicates the presence of HSV, the woman should be notified, and a discussion regarding further diagnostic testing should occur.

Many laboratories report a predominance of coccobacilli consistent with a shift in vaginal flora. Some clinicians consider this finding suggestive of bacterial vaginosis. Bacterial vaginosis is multibacterial in origin and cannot be diagnosed via cytology. When coccobacilli are identified on a Pap report, the midwife can inquire whether the woman is symptomatic, and offer an examination to assess for bacterial vaginosis. Current research findings are inconsistent concerning the value of screening asymptomatic women for bacterial vaginosis.

A finding of *Actinomyces* on a Pap test result for a woman who is using intrauterine contraception should be further evaluated. *Actinomyces* is a strain of bacteria found in the normal genital tract. In rare cases, its presence has been associated with the development of pelvic inflammatory disease and pelvic abscess in women using intrauterine contraception. If infection is likely or the woman is symptomatic, the intrauterine device (IUD) should be removed and antibiotics initiated. If the woman is asymptomatic, the device can be left in place, and antibiotic treatment is not indicated.[20,21]

To summarize, the purpose of the Pap test is to detect cervical cancer and categorize epithelial cell abnormalities. The Pap test is a *screening*, rather than a diagnostic test. If the clinician visualizes an unusual lesion or mass on the cervix, a Pap test can be performed as an initial step in evaluation. While a variety of incidental findings may be noted on a Pap report, these findings are not diagnostic. Additional follow-up may be needed depending upon the report, the woman's symptoms, and/or abnormal findings during the examination.

Alternative Methods of Cervical Cancer Screening in Low-Resource Areas

In many countries without Pap test screening systems, cervical cancer is a significant cause of death among women. An alternative method used for screening is visual inspection with either a 5% solution of acetic acid or Lugol's iodine solution. This technique involves the application of the agent during a speculum examination and examination of the cervix with the naked eye to identify lesions that appear acetowhite when exposed to acetic acid, or bright yellow when exposed to Lugol's solution. This test is usually conducted by trained lay health workers, making the technique cost-effective and accessible to large populations of women who might not otherwise be screened during their lifetime. Referral is indicated after discovery of abnormal lesions.[22,23]

Another method to screen for cervical cancer sometimes used in low-resource countries is cervicography. This method uses low-magnification photographs of the cervix, now available in digital format, which are interpreted by a cytopathologist, frequently at a different site and later in time. Women with abnormal cervigrams are referred for further evaluation and treatment. This method is not as sensitive or specific as colposcopy, but evidence shows that this technique has a high negative predictive value and serves an important role in cervical cancer screening in locations where cytology screening is unavailable.[24]

Diagnosis and Treatment for Women with Abnormal Pap Test Results

The 2012 guidelines recommended by the American Society for Colposcopy and Cervical Pathology (ASCCP), Society of Gynecologic Oncology (SGO), and American College of Obstetricians and Gynecologists (ACOG) form the basis for management of Pap test findings, as well as the management proposed by ACOG for abnormal cervical cancer screening test results.[13-15] The midwife's role in managing a woman with Pap test results can range from immediate referral to performance of follow-up tests, including colposcopy, depending on the midwife's formal preparation, experience, institutional guidelines, and skill level. If the results of a Pap test include findings such as carcinoma in situ, squamous cell carcinoma, or adenocarcinoma, immediate referral of the woman to a gynecologic oncology specialist is indicated.

Factors such as age, HPV status, pregnancy, previous Pap tests, past treatments, and histologic results may all affect Pap test management, making it complex. For example, the ASCCP guidelines include more than a dozen discrete algorithms based on the Pap test results, describing how to manage women with all of the following: unsatisfactory cytology, absent endocervical cells, ASC-US, LSIL, HSIL, atypical glandular cells, cervical intraepithelial lesions, and adenocarcinoma in situ. More-frequent screening may be indicated for women with HIV and other immunosuppressed conditions such as organ transplant, women exposed to diethylstilbestrol (DES) in utero, and those with a history of prior treatment for CIN 2, CIN 3, or cervical cancer. The ASCCP guidelines are available free of charge and are updated on a regular basis; a link to these guidelines and information about accessing them are provided in the Resources section at the end of this chapter.[13]

Colposcopy

The primary diagnostic method for determining the presence of cervical cancer or precancerous cells is colposcopic examination. Although a detailed description of the procedure is beyond the scope of this chapter, an increasing number of midwives are receiving formal education in performing colposcopy and have formally incorporated the procedure into their clinical practices as congruent with Standard VII in the *ACNM Standards for the Practice of Midwifery*.[25] Principles and standards of colposcopy education and practice for all clinicians are now established and endorsed by several women's health professional organizations.[26] Common indications for colposcopy are listed in **Table 12-3**.[14,17,27]

Table 12-3	Common Indications for Colposcopic Examination of the Cervix
Grossly visible or palpable abnormality of the cervix	
Abnormal cervical cytology	
Positive screening test for cervical neoplasia (e.g., high-risk HPV DNA strain)	
Persistent unsatisfactory cervical cytology	
History of in utero DES exposure	
Unexplained cervicovaginal discharge	
Unexplained abnormal lower genital tract bleeding	

Surveillance for lower genital tract neoplasia (cervical, vaginal, vulvar)
Post–lower genital tract cancer treatment surveillance

Abbreviations: DES, diethylstilbestrol; DNA, deoxyribonucleic acid; HPV, human papillomavirus.

Based on American College of Obstetricians and Gynecologists. Follow-up of women with negative Pap test results and abnormal clinical signs or symptoms. *Am J Clin Pathol.* 2016;145:560-567.[27]

When lesions of the vulva, vagina, or ectocervix are identified during colposcopy, a biopsy is performed at the same time. Endocervical curettage is recommended in certain situations (e.g., no lesion is found during a satisfactory colposcopy examination) to evaluate tissue not easily visible on the ectocervix. The purpose of a tissue biopsy or endocervical curettage is to rule out cancer or precancerous lesions, and subsequently guide treatment.

The choice of treatment depends on the size, location, and significance of the abnormality (CIN 1, 2, 3, or cancer), the woman's age, and her desire for future childbearing. As with any gynecologic procedure, it is important to engage in shared decision making and obtain signed informed consent.

Gynecologic Evaluation and Pelvic Pain

Reports of abdominal and/or pelvic pain are common motivations for seeking gynecologic care and account for a significant number of visits to healthcare providers. This section introduces the initial gynecologic evaluation and common differential diagnoses in women of reproductive age.

Acute Pain

Acute abdominal or pelvic pain is a medical emergency. The ability to provide safe care for a woman experiencing acute pain requires that the midwife have relationships with surgical and nongynecologic providers and a system for referral. Careful screening and triage must be done to determine the optimal setting for evaluation of acute pain to ensure appropriate management; this setting may be an emergency department or a targeted visit in an office setting, depending on how stable the woman is and which other resources are available or needed for a thorough evaluation. Immediate consultation/referral is indicated for a woman with acute pain, especially if her pain is accompanied by fever, tachycardia, significant changes in blood pressure, signs of shock, vomiting, unstable vital signs, or evidence of significant blood loss.

Chronic Pain

Chronic pelvic pain may arise secondary to one or several underlying disorders, and it can be difficult to evaluate and treat.[28-30] The woman with chronic pelvic pain may have a history of multiple encounters with healthcare providers. It is crucial to know if a woman has been evaluated for chronic pain previously and to clarify her expectations for midwifery involvement in care. Because chronic pelvic pain is associated with multiple underlying etiologies, women with chronic pain are often best cared for by gynecologists who specialize in this condition. A general understanding of chronic pelvic pain can help a midwife participate in evaluation and team-based care for these women.

Sexual Abuse and Assault

A person who has experienced sexual abuse or trauma may have unique gynecologic needs. When caring for individuals who have been sexually abused or assaulted, it is essential for the midwife to provide care that addresses the person’s needs in a manner that does not add to physical discomfort, emotional distress, or trigger a recurrent sense of trauma.[31] An objective and straightforward explanation of the examination should occur before the woman takes off her clothes. Patience and use of skills in facilitating relaxation are indispensable. If abuse is known or revealed during the visit, the midwife should offer to ensure the presence of another staff member or a support person for the examination, in an effort to give the woman a feeling of some control over the procedure.

If it is difficult for the woman to proceed with a physical examination, it may be conducted in smaller steps, over more frequent encounters when possible, unless there is concern about an acute or emergent problem. If the problem appears to be acute, the midwife should assess

which type of examination other providers may need to do and limit the current examination to only those elements that are absolutely necessary for consultation or referral. For example, if a woman has been recently assaulted, it may be necessary to ask a Sexual Assault Nurse Examiner (SANE) to conduct the examination. Some midwives are SANE certified and may perform a complete forensic examination, including collection of evidence.

Regardless of the reason for the visit, the midwife should clearly acknowledge the person's experience and offer the office as a safe haven for exploration and healing.[32] Suspicion or evidence of physical or sexual abuse or assault requires the midwife to follow institutional guidelines and laws of the jurisdiction where the midwife is practicing, including those that dictate the legal authority to which the midwife must report any suspicion or evidence of abuse or assault.

Differential Diagnoses Associated with Pelvic Pain

Multiple disorders are associated with abdominal pain, pelvic pain, or both. The list of candidates varies depending on a person's age (e.g., premenopausal or postmenopausal) and other demographic characteristics. Common differential diagnoses to be considered for individuals of reproductive age who present with acute or chronic abdominal or pelvic pain are listed in **Table 12-4**.[33] This list can be used to suggest components of the physical examination. Because the list of differential diagnoses is large, three initial assessments will help focus the direction of the evaluation:

Table 12-4	Selected Differential Diagnoses of Acute or Chronic Abdominal and/or Pelvic Pain in Women[a]
System	**Differential Diagnoses**
Gastrointestinal	Appendicitis Bowel obstruction Crohn's disease Constipation Diverticulitis Gallbladder obstruction Inflammatory bowel disease or irritable bowel disease Pancreatitis
Musculoskeletal	Fibromyalgia Herniated disc Hernia Pelvic pain syndrome Sprain or strain
Gynecologic, acute pain in nonpregnant woman, not at risk for pregnancy	Endometriosis (rupture of endometrioma) Dysmenorrhea Intrauterine device imperforation Mittelschmerz Ovarian cyst Pelvic inflammatory disease

	Torsion or degeneration of uterine fibroids
Gynecologic, chronic pain in nonpregnant woman, not at risk for pregnancy	Adenomyosis Adhesions Endometriosis Malignancy Prior pelvic inflammatory disease Ovarian cancer Uterine fibroid
Gynecologic, fertility treatment	Ectopic pregnancy Ovarian hyperstimulation syndrome Ovarian cyst Ovarian torsion
Pregnancy-related	Corpus luteal cyst Ectopic pregnancy Normal pregnancy nausea and vomiting Ovarian torsion Miscarriage Preterm labor or placental abruption
Postmenopausal	Malignancy
Urologic	Interstitial cystitis Pyelonephritis Urinary retention/obstruction Urinary tract infection

[a] This list is not comprehensive. These disorders are included here because they are either commonly encountered or not common but associated with severe morbidity and, therefore, essential considerations during an evaluation.

1. Is the woman premenopausal or postmenopausal?
2. Could she be pregnant or attempting pregnancy?
3. What are the characteristics of the pain and associated symptoms?[34]

Evaluation of a Woman with Abdominal/Pelvic Pain

In all settings, the role of midwifery care when evaluating a person with abdominal or pelvic pain includes a thorough history, physical examination, initial laboratory evaluation, and referral for specialist care as needed.

A helpful tool in the evaluation of any symptom, including pain, is the OLD CARTS system (**Table 12-5**).[34] Use of common validated questionnaires is also recommended when assessing a woman with chronic pain.[35] Some women will answer questionnaires in detail and provide a wealth of information; however, others who have not considered their pain in a comprehensive manner may need to return for a future visit after completing a pain diary or history.

Table 12-5 OLD CARTS Mnemonic for Obtaining a History of Reported Pain

Desired	Questions to Be Asked

Information	
Onset	When did the pain begin? Can the woman identify a particular event or point in time related to the initial recognition of the pain?
Location/radiation	Specifically identify the location of the pain. Does the pain move or radiate or have a different quality in varying locations?
Duration	Is the pain cyclic or noncyclic? Is it related to other health factors (e.g., bowel function, physical activity, sexual activity, menstrual cycle)? Is the onset of the pain related to diet or diet changes? Is it related to work activities? Is it related to the woman's emotional state of being or to the onset of emotional stress?
Character	Ask the woman to describe the pain. Offer a wide variety of descriptors used for pain, such as *sharp, dull*, *gnawing*, *burning*, or *achy*.
Aggravating factors	What makes the pain worse (e.g., exercise, diet, constipation, diarrhea, urination, physical activity, sexual activity, menses)?
Relieving factors	What relieves the pain (e.g., rest, diet change, bowel movement), and to what degree? Which treatments have been used to help alleviate the pain? Were they recommended by other providers or suggested by a family member, friend, book, or website? Were medications used (over-the-counter and/or prescription)? Were any alternative treatment modalities used? What was the success or failure of any treatments that were used?
Timing factors	How often is the pain occurring? Was there a single incident, or is the pain intermittent or chronic in nature? Have the symptoms improved or worsened over time? Is there a specific time of day when the pain is felt more often?
Severity	How severe is the pain on a scale of 0 to 10, with 10 being the worse pain the woman can imagine? Has the pain had an effect on the woman's lifestyle? On her ability to work?

Based on Ball J, Dains J, Flynn J, Solomon BS, Stewart RW. *Seidel's Guide to Physical Examination.* 8th ed. St. Louis, MO: Mosby Elsevier; 2015.[34]

Many causes of acute pain can become causes of chronic pain. For example, 30% of women with pelvic inflammatory disease develop chronic pelvic pain.[36] Finally, it is always important to ask two initial question: What does the individual think is causing the pain? And, how is the pain affecting their quality of life? If the initial history results in an inability to diagnose the cause of pain and the woman wishes to continue investigation with the midwife, a more detailed history of the pain can be suggested. Assessment modalities may include anatomic drawings used to locate the pain; the use of a pain diary with a pain severity scale; or the use of a journal to additionally chart the pain in relation to daily activities, menstrual cycle, bowel habits, sexual activity, and diet.

Physical Examination

Examination of a woman presenting with pelvic pain may require a complete physical examination. Many gynecologic disorders will manifest in different ways, including pain in the abdomen, in the pelvis, or both. If a more narrowly focused examination is indicated, vital signs and both abdominal and pelvic examinations should be performed, and the results documented in the woman's health record. In the absence of an acute presentation, a complete examination of systems can be performed. The woman's demeanor and presentation are included in this evaluation. Evaluation of the back and lower extremities is included to rule out a musculoskeletal injury, such as a muscle strain or stress fracture, or an anatomic variation,

such as scoliosis.

Abdominal Examination

The goal in palpation of the abdomen is to identify organ enlargement, displacement, masses, or enlarged lymph nodes as well as to ascertain if and where the pain can be elicited. The midwife can ask the woman if she can elicit the pain herself. If not, it is advisable to focus on the unaffected side or area first. Communicating findings and letting the person know which part of the examination is next can help maintain an atmosphere of trust and caring. Special attention should be paid to any area of tension or guarding, and knowledge of patterns of referred pain points is useful as well.

Pelvic Examination

At the time of visual inspection of the vulva and vagina, signs of swelling, lesions, trauma, or other skin changes can be assessed. The woman's ability to tolerate a speculum insertion with or without pain is an important observation, especially if she reports pain with sexual activity. After speculum insertion, a sample of vaginal discharge is collected for a saline or KOH examination or cultures, and subsequent testing for sexually transmitted infections (STIs) if indicated. Visual inspection of the cervix may reveal a partially expelled IUD, signs of infection, color change indicative of early pregnancy, laceration, a polyp, or other abnormality.

After the speculum examination is complete, a gentle bimanual examination enables the midwife to observe whether the woman exhibits discomfort at the introitus versus deep in the vagina or pelvis. Any cervical, adnexal, or uterine motion tenderness elicited provides further information in addition to signs of organ displacement.

Palpation for any masses, uterine fibroids (leiomyomata), or uterine or adnexal enlargement indicative of pregnancy is the next step. Assessment of pelvic muscle tone is performed, and the presence of a cystocele, a rectocele, or uterine prolapse is ascertained. Confirmation of findings can be accomplished with a rectal examination as well as assessment for hemorrhoids, polyps, or masses.

Recorded descriptions of a mass or enlarged organ should include the size, shape, location, consistency, mobility, tenderness, and relationship of the mass to other organs. Additionally, if pain is elicited, its intensity and location should be described. If the woman's pain limits the midwife's ability to perform full palpation and/or pelvic examination, that finding should be documented as well.

Laboratory/Screening/Diagnostic Tests

Only tests that will generate results which could directly influence management should be performed. A pregnancy test is inexpensive and generally indicated for any sexually active reproductive-age woman regardless of contraceptive method used. A complete blood count is often ordered as a standard test; however, in the absence of heavy vaginal bleeding, an infectious process, or concerns about anemia, this test may not be useful. If the cause of the pain is considered urologic in nature, a urinalysis or urine culture may be informative. Tests

for STIs or vaginitis may be indicated by history and examination. A fecal occult blood test may aid in the management of any abdominal mass or gastrointestinal condition. Any fetal occult blood test that is positive should result in referral to a specialist for further evaluation and possible colonoscopy or sigmoidoscopy testing.

A pelvic or abdominal ultrasound is commonly used to aid in the diagnosis of uterine or adnexal abnormalities. If an ultrasound is ordered, a transvaginal ultrasound may be more accurate than a transabdominal approach. For women who have never experienced vaginal penetration, women who have cultural prohibitions with regard to pelvic procedures, or those with a personal history of sexual assault trauma, this part of the test may be distressing. Anticipatory guidance includes an explanation of the reason for using ultrasound and shared decision making. If the woman wishes to have the ultrasound performed, it is important to alert staff who may be working with the woman that this is an initial transvaginal pelvic ultrasound and that additional patience and time may be necessary.

Adnexal Masses in Reproductive-Age Women

Adnexal masses are common and frequently found incidentally during a regular pelvic examination. The differential diagnosis of an adnexal mass includes a physiologic cyst (e.g., corpus luteum), ectopic pregnancy, benign ovarian neoplasms (e.g., dermoid cyst), ovarian cancer, tubo-ovarian abscess, endometriosis, or ruptured cyst.[37] Adnexal masses may be found in both premenopausal and postmenopausal women. Women may be asymptomatic or they may present with symptoms of pelvic pressure, pain, or dyspareunia. Some symptoms associated with ovarian cysts may be vague, such as abdominal bloating, a sensation of fullness, or, possibly, urinary frequency or retention.

Pelvic examinations are often inadequate to determine the size, location, and characteristics of an adnexal mass. Such examinations are especially inadequate for identifying ovarian cysts in women with obesity. Ultrasound and magnetic resonance imaging (MRI) are the most commonly used imaging modalities for assessment of the size, character, and malignant characteristics of adnexal masses.

Corpus Luteum Cysts

Corpus luteum cysts develop following hemorrhage of the corpus luteum, most often during days 20–26 of the menstrual cycle. Ultrasound may confirm the diagnosis. In the absence of bleeding, the cyst will regress spontaneously. In the event of significant bleeding, or with acute pain secondary to the bleeding, a negative pregnancy test may assist in differentiating a ruptured corpus luteum cyst from an ectopic pregnancy. If bleeding continues, surgical intervention may become necessary.

Ectopic Pregnancy

Ectopic pregnancy is any pregnancy implanted outside the endometrial cavity. An ectopic pregnancy is considered a life-threatening emergency, even if the woman appears stable and asymptomatic. Thus, ectopic pregnancy is one of the first differential diagnoses to be considered in any reproductive-age woman. Suspicion for an ectopic pregnancy should be high if a woman reports amenorrhea or intermittent abdominal or pelvic pain of varying duration and intensity. Furthermore, women who present with any of these symptoms in addition to shoulder pain (i.e., referred pain secondary to the presence of blood in the abdominal cavity, fever, tachycardia, or low blood pressure) must be evaluated for shock and emergency referral even in the absence of vaginal bleeding. The woman with an ectopic pregnancy may have not suspected she was pregnant and may be required to integrate a great deal of information at a very stressful moment. More discussion of ectopic pregnancy is found in the *Pregnancy-Related Conditions* chapter. **Table 12-6** summarizes the elements to be included in a transfer note for a woman who may have an ectopic pregnancy.

Table 12-6 Critical Elements for a Transfer Note for a Woman Suspected with an Ectopic Pregnancy

Signs and symptoms suggestive of ectopic pregnancy, including last menstrual period and any risk factors (e.g.,

pregnancy with intrauterine device in situ)

Care provided before transfer: procedures and results; laboratory results or if pending; pregnancy test results and sonography findings

Assessment/diagnosis of the situation

Summary of rationale for transfer and request for information about the treatment plan for follow-up

Ovarian Cysts

The management of women with ovarian cysts is based on the presence of symptoms, results of imaging, the woman's age, medical history, physical examination, and blood work. The cyst is first classified as simple or malignant based on features identified on ultrasound.[37] Cysts that have both benign and malignant features require further evaluation to determine the risk for malignancy. Simple ovarian cysts that are thin walled, unilocular, and small are usually benign, but may best be followed with periodic ultrasound assessment. The Society of Radiologists in Ultrasound has published guidelines for management of asymptomatic ovarian cysts detected on ultrasound; these guidelines are based on the woman's premenopausal or postmenopausal status, size, and characteristics.[38,39]

Dermoid Cysts

Dermoid cysts or cystic teratomas are asymptomatic, unilateral ovarian masses that arise from all three germ cell layers (ectoderm, endoderm, and mesoderm) and, therefore, may contain skin, bone, hair, and teeth. Dermoid cysts are generally asymptomatic and first identified during a pelvic examination or ultrasound. Such cysts do not regress and have a small chance of becoming malignant; therefore, the treatment is surgical removal.

Ovarian Torsion

An uncommon cause of acute pelvic pain is ovarian torsion, also referred to as adnexal torsion. While causes of torsion include previous adnexal surgical manipulation (especially tubal ligation), an adnexal structural anomaly, or pregnancy, the majority of cases are related to ovarian or adnexal masses. The woman may present with specific pain or more generalized unilateral pelvic or flank pain, as well as nausea and vomiting.[40] This condition often can be confused with gastrointestinal disorders.

The treatment of a woman with ovarian torsion is surgery, during which the ovary is fixed in place or removed depending on the etiology, if evident, and the presence of tissue damage or necrosis. False-positive diagnoses of ovarian torsion based on ultrasound are not uncommon. In such a case, the pain may be due to endometriosis, ovarian enlargement without torsion, or unknown causes not readily apparent.

Disorders of Uterine Origin

The most common disorders associated with the uterus include endometriosis and uterine fibroids. A less common disorder is adenomyosis.

Endometriosis

Endometriosis is the presence of endometrial tissue outside of the uterine cavity. Although it has been difficult to gauge the prevalence of this condition, it is estimated to affect as many as 15% of women of childbearing age.[41] The incidence is higher in women who present with infertility and chronic pelvic pain. Associated risk factors include a family history, early age at menarche, frequent menses, nulliparity, a history of other pain syndromes (e.g., interstitial cystitis, bladder pain syndrome), inflammatory bowel disease, and a diagnosis of immunologically impaired conditions (including asthma and allergies).[41]

The American Society for Reproductive Medicine (ASRM) categorizes endometriosis into one of four stages depending on location(s), depth of the endometrial lesions (implants), extent of the implants, presence of adhesions, and presence of ovarian endometriomas (a type of ovarian cyst):[42]

- Stage I: Minimal; characterized by few implants and no adhesions
- Stage II: Mild; characterized by superficial implants, and no significant adhesions
- Stage III: Moderate; characterized by the presence of both superficial and deep implants, as well as notable adhesions
- Stage IV: Severe; characterized by multiple implants, dense adhesions, and an association with infertility

Unfortunately, these stages do not correlate with the severity of symptoms or infertility.[43] Despite the limitations of the ASRM system, it is helpful as a uniform classification of surgical findings.

The cause of endometriosis remains elusive, and multiple etiologic theories have been proposed, as listed in **Table 12-7**.[44-48] Retrograde menstruation followed by extrauterine implantation remains the oldest and most widely supported theory, although findings of endometriosis implants in pre-menarche adolescents suggest more than one etiology. Findings during laparoscopy have revealed that during menses, endometrial tissue migrates into the peritoneal cavity via the fallopian tubes, attaching itself to the pelvic organs. However, this finding does not explain all cases of endometriosis that have been documented. Indeed, retrograde menstruation commonly occurs, and is more prevalent than the presence of endometriosis. Thus, there is support for theories suggesting that additional factors—such as hormonal, inflammatory, or immunologic conditions—contribute to the actual development of endometriosis in a subpopulation of individuals.[48]

Table 12-7	Proposed Etiologies of Endometriosis

Proposed Etiology	Rationale
Retrograde menstruation	During menses, endometrial tissue migrates into the peritoneal cavity, via the fallopian tubes, attaching itself onto pelvic organs.
Deviations in cellular physiology	Peritoneal tissue is spontaneously transformed into endometrial tissue.
Deviations in lymphatic system	Endometrial tissue is transported to other organs via the lymphatic pathways.
Deviations in immune system	Menstrual tissue found outside the uterus is normally cleared by the immune system, which appears unable to do so in individuals found to have endometriosis.
Deviations in hormonal system	Unlike in intrauterine endometrial tissue, the estrogenic effects of extrauterine endometrial tissue are not influenced by the antagonistic action of progesterone.
Genetics	A 3 to 9 times increased incidence is found among first-degree relatives of affected individuals (i.e., mothers or siblings) compared to the incidence found in the general population.
Environmental influences	Dioxin-like compounds discovered in industrial waste by-products can alter gene development or estrogen–progesterone balance in a manner that leads to extrauterine development of endometrial tissue.

Based on Burney RO, Giudice LC. Pathogenesis and pathophysiology of endometriosis. *Fertil Steril.* 2012;98:511[45]; Rahmioglu N, Nyholt DR, Morris AP, Missmer SA, Montgomery GW, Zondervan KT. Genetic variants underlying risk of endometriosis: insights from meta-analysis of eight genome-wide association and replication datasets. *Hum Reprod Update.* 2014;20:702-716[46]; Parazzini F, Esposito G, Tozzi L, Noli S, Bianchi S. Epidemiology of endometriosis and its comorbidities. *Eur J Obstet Gynecol Reprod Biol.* 2016;209:3-7[47]; Rice K, Secrist J, Woodrow E, Hallock L, Neal J. Etiology, diagnosis, and management of uterine leiomyomas. *J Midwifery Womens Health.* 2012;57;241-247.[49]

Endometriosis is associated with a number of symptoms—most commonly pelvic pain (particularly dysmenorrhea), dyspareunia, and infertility. However, because endometrial tissue can be found in or proximate to a dozen extrauterine sites (**Figure 12-1**), symptoms can also include lower back pain, heavy menstrual bleeding (menorrhagia), irregular menses, pain between menstrual cycles, dysuria, constipation or diarrhea, postcoital bleeding, lower abdominal pain associated with ovarian cysts, and chronic fatigue. Surgeons also may discover endometriosis among asymptomatic women incidental to an unrelated pelvic surgery or procedure.

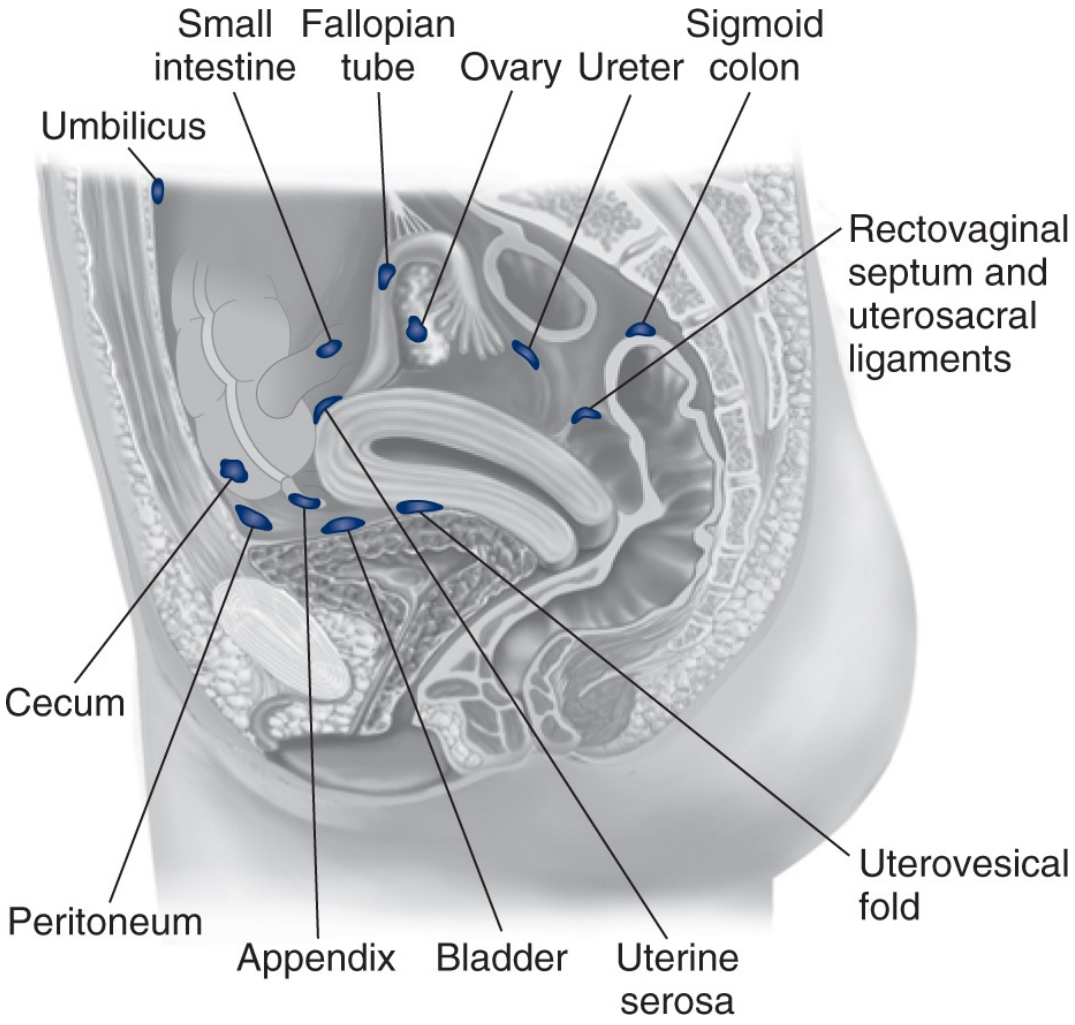

Figure 12-1 Possible locations in which extrauterine endometrial tissue may be found.

Pelvic or lower abdominal pain due to endometriosis may be related to the menstrual cycle, typically appearing at ovulation or intermittently in the time between ovulation and menses. The pain may continue throughout the menses. Pain associated with endometriosis may also occur in patterns unrelated to the menstrual cycle. For example, pain during or after coitus may be so severe as to preclude sexual activities.

Physical examination findings in a woman with endometriosis may be normal, with no significant tenderness associated with organ palpation or movement. In other cases, however, the woman may have cervical motion tenderness, bilateral or unilateral adnexal tenderness, tender nodules on the uterosacral ligaments, ovarian enlargement, or a fixed, retroverted uterus. Definitive diagnosis requires visualization of endometrial implants during surgery. Confirmation of the diagnosis requires biopsy and guides the direction of future treatment. The use of imaging, such as MRI and transvaginal ultrasonography, may provide diagnostic information when the woman has advanced endometriosis; however, these imaging techniques are not useful to identify small or early lesions.

The treatment(s) for endometriosis have mixed success. Providers may select a combination of pharmacologic and surgical therapy, including complete hysterectomy and oophorectomy.[44,48] Pharmacologic treatments include pain relief measures such as use of

nonsteroidal anti-inflammatory drugs (NSAIDs), which suppress hormonal stimulation of the endometrial tissue. Combined or progestin-only hormonal contraceptives and gonadotropin-releasing hormone (GnRH) agonists have the same effects as NSAIDs. Surgical procedures can also be performed to remove lesions. The treatment employed depends on the wishes of the woman including her desire for future childbearing, the degree of pain, the effects of endometriosis on her quality of life, the degree to which her fertility is affected and her age. A multidisciplinary approach is recommended. Small lesions may be removed during the diagnostic laparoscopy followed by hormonal treatment to suppress further growth of the disease, and the use of individually tailored pain management strategies.

Leiomyomas (Uterine Fibroids)

Leiomyomas, also known as uterine fibroids or fibromyomas, are benign smooth muscle tumors that develop from uterine smooth muscle. Uterine fibroids are very common, with a prevalence that ranges from approximately 60% in white women to 80% in black women. As many as 50% of women with fibroids have symptoms, including heavy menstrual bleeding (menorrhagia), pelvic pain, dyspareunia, or urinary frequency if the tumor presses anteriorly on the bladder.[49-51] Thus, half of women with fibroids may never know of the tumors' presence and remain asymptomatic across their lifespan.

Estrogen and progesterone promote fibroid growth and theoretically could facilitate growth in size during pregnancy, although most research has found that fibroids visualized on ultrasound either remain the same size or decrease in size during pregnancy.[51] Generally, fibroids regress after menopause. While fibroids are rarely associated with the development of cancer, any postmenopausal growth of a fibroid or accompanying symptoms, particularly uterine bleeding, warrants evaluation for possible leiomyosarcomas.[51]

Leiomyomas are described on the basis of their anatomic location.

- *Subserosal fibroids* exist just under the uterine serosa and are located outside of the uterus. These growths are attached to the uterus by a large or small base and may be easily palpated on abdominal examination.
- *Intramural* or *myometrial fibroids* are located within the uterine myometrium and may give the uterus an irregular contour.
- *Submucosal fibroids* are located in the uterine endometrium and are usually palpable only as an enlarged uterus.
- *Pedunculated fibroids* present either outside or within the uterine cavity.

When fibroids are present, the uterus will feel firm and irregularly shaped during palpation. If fibroids are suspected during an examination, this finding is shared with the woman and confirmed via an ultrasound examination. The benign nature of fibroids is reviewed, as fears of cancer are possible whenever a woman is told she may have an unexpected mass. **Figure 12-2** depicts fibroids in relation to the uterus as determined by diagnostic imaging or at the time of surgery.

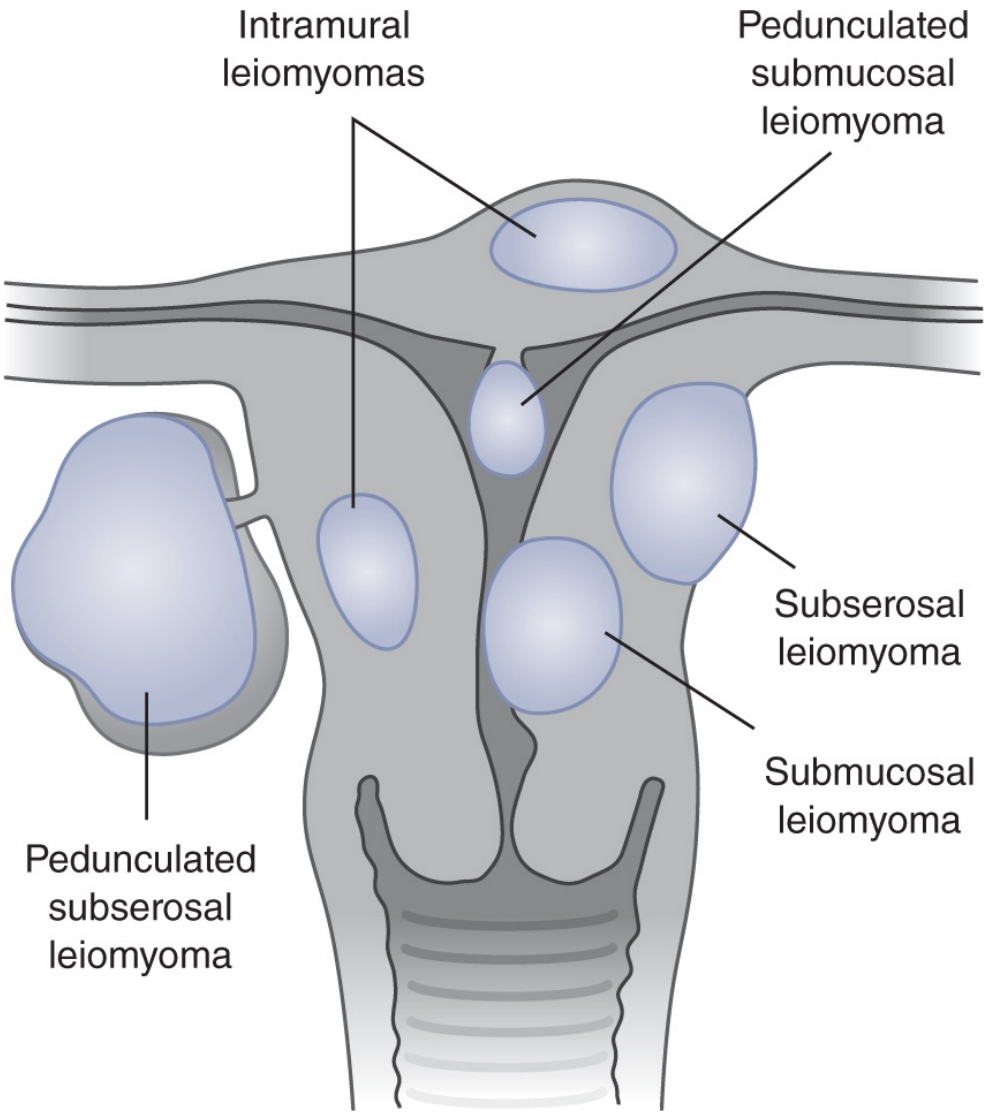

Figure 12-2 Classification of fibroids (leiomyomas) by location in relation to the uterus.

Women with slow-growing fibroids may gradually become accustomed to feelings of pelvic fullness and report few symptoms or little pain, even though fibroids may be large. Other women may present with chronic pelvic pain, lower abdominal pressure, or abnormal uterine bleeding. Fibroids can cause urinary frequency, rectal pressure, interference with sexual activity, and dyspareunia. Depending on their location, these masses can cause infertility, spontaneous abortion, premature labor, malpresentation of a fetus during pregnancy or labor, or an abnormal labor progress.[50,51] Fibroids may also be implicated in abnormal uterine bleeding, especially during the perimenopausal stage of a woman's life. The presence of large fibroids or the degeneration of fibroids may cause pain, including during pregnancy.

Treatment of women with fibroid-related pain depends on the situation and severity of symptoms. Expectant management is recommended for most women, as many fibroids may never be associated with symptoms and most regress after menopause.[50,51] A careful documentation of fibroid size and shape at each annual examination, along with a review of any change in symptoms, is an acceptable management plan.

When intervention is necessary, a variety of nonsurgical interventions, including

pharmacologic agents, can be employed to preserve the uterus.[50,51] Alternative therapies, including the use of acupuncture, bodywork, imagery, and traditional Chinese medicine have been the subject of some research, but results of this body of work are inconclusive.[49,51]

Pharmacologic methods for treating fibroids include the traditional use of GnRH agonists (e.g., leuprolide acetate [Lupron]) as well as the levonorgestrel-releasing IUD. Success rates in diminishing the size or symptoms of fibroids vary considerably with these methods. While the use of GnRH agonists may be most effective, significant side effects preclude their first-line use because they induce menopausal symptoms.[51] However, if surgery is deemed appropriate, a GnRH agonist may be used preoperatively to shrink the fibroid(s). Smaller fibroids are easier to remove, and any reduction in size prior to surgery may give the woman the option of a vaginal versus an abdominal hysterectomy procedure.

Myomectomy is recommended to women with pain or other indications for fibroid removal who also wish to maintain fertility. While a variety of surgical techniques have emerged in recent years, including uterine artery embolization (UAE) and ultrasonography ablation, each method requires individualization depending on the preference of the woman and the characteristics of the fibroid. In the case of large fibroids, persistent heavy vaginal bleeding, or refractory anemia, hysterectomy remains a common treatment option. Midwives should collaborate with specialists in the care of women who are experiencing fibroid-related pain during pregnancy, as a myomectomy during pregnancy may be needed.[49]

Adenomyosis

Unlike fibroids, which are composed of uterine smooth muscle, adenomyosis results from the growth of endometrial tissue in the myometrium layer of the uterus, typically causing uterine enlargement. Because adenomyosis involves growth of endometrial tissue, this condition is considered by some to be a form of endometriosis.[52] Two forms of adenomyosis have been identified: (1) diffuse adenomyosis, in which endometrial tissue is found throughout the myometrium; and (2) focal adenomyosis, in which one or more nodular lesions, known as adenomyomas, are located in specific areas of the uterine myometrium. Diffuse adenomyosis is the more common of the two forms, and is found in approximately two-thirds of diagnosed cases.[53]

Due to difficulty in diagnosing adenomyosis, reports of the incidence of this disorder vary widely—between 20% and 35% of biologic females.[52,53] While many individuals with adenomyosis are asymptomatic, one-third of persons with this diagnosis report menorrhagia, dysmenorrhea, and dyspareunia. In general, most women with adenomyosis have given birth and typically develop the condition in their fourth or fifth decade of life. Transvaginal sonography can be helpful in diagnosing adenomyosis, although the more definitive diagnostic tool is MRI.

Because the symptoms most commonly associated with adenomyosis are heavy menstrual bleeding and dysmenorrhea, traditional pharmacologic treatments include NSAIDs and combined oral contraceptives. However, greater success is reported with use of progestin-only agents, GnRH agonists, tranexamic acid (Lysteda), and levonorgestrel-releasing IUD. Reduction of symptoms with these approaches varies, and the clinician should be familiar with

the risks, benefits, and contraindications of each approach before recommending it. For example, tranexamic acid, a blood clotting agent, is contraindicated for women with a history of venous thromboembolism or women who are using a combined hormonal contraceptive method because tranexamic acid increases the risk of thrombosis. Other approaches include uterine artery embolization and radiofrequency ablation (RFA)—techniques also used to treat fibroids.[54] However, if various therapies have been attempted, with few positive results, the definitive treatment for adenomyosis is hysterectomy.[52]

Uterine Cervical Variations and Disorders

The cervix undergoes cellular maturation and repair processes throughout a woman's lifetime.[55] Inspection of the cervix with the naked eye during the course of a pelvic examination may reveal several normal and abnormal features relative to the woman's age; hormonal status; contraceptive method; stage of pregnancy; and presence or absence of inflammation, infection, or disease. The size and shape of the cervical os is largely determined by parity. **Figure 12-3** and **Figure 12-4** illustrate common variations noted when visualizing the cervix—specifically, nabothian cysts, cervical ectopy, polyps, and cervical lacerations.

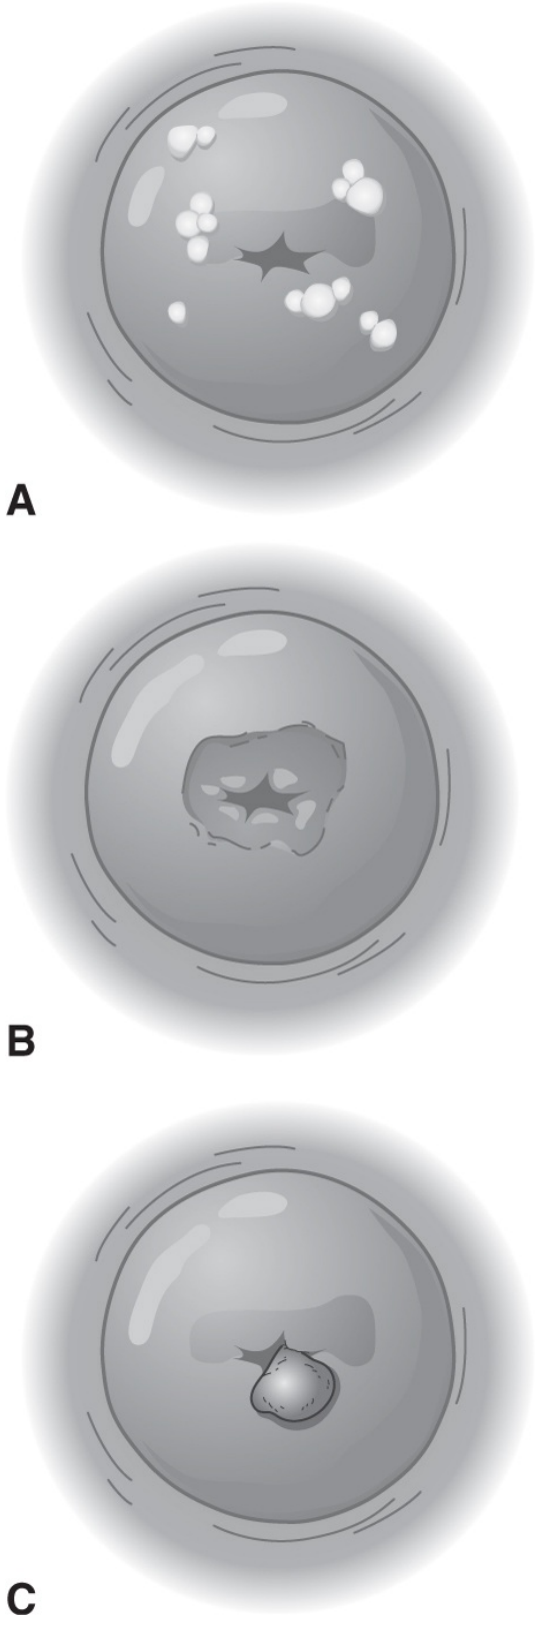

Figure 12-3 **A.** Nabothian cyst. **B.** Cervical ectopy. **C.** Endocervical polyp.

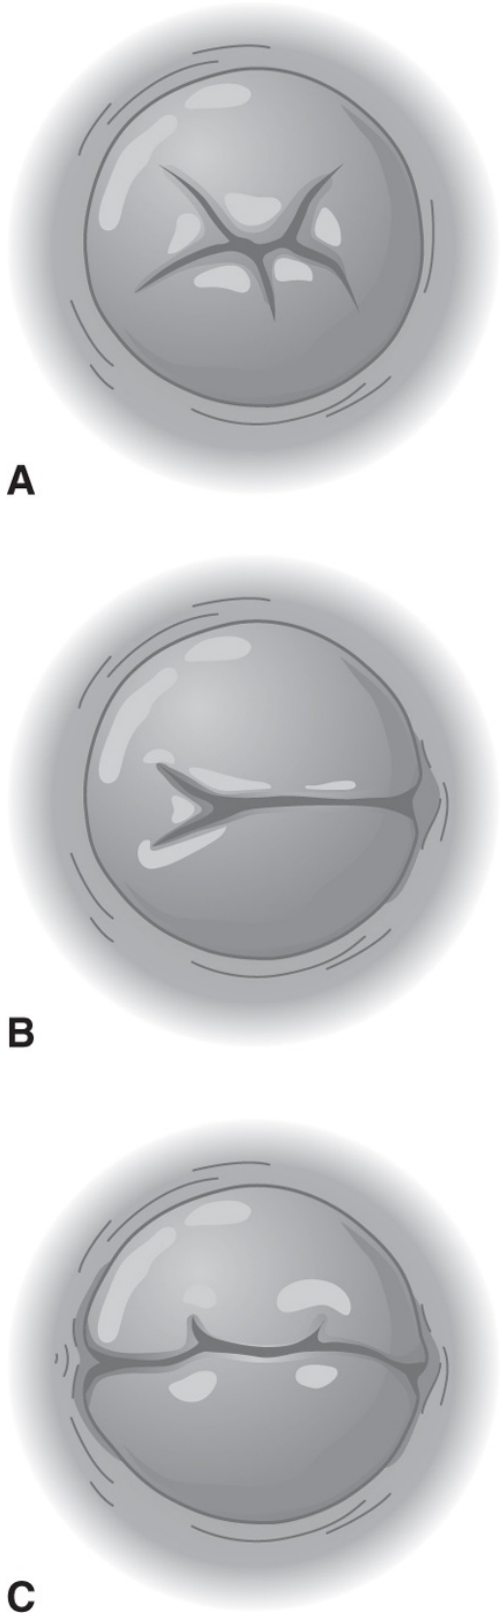

Figure 12-4 Cervical lacerations. **A.** Stellate. **B.** Unilateral transverse. **C.** Bilateral transverse.

Nabothian Cysts

Nabothian cysts, also referred to as mucus cysts or epithelial cysts, are often seen on the cervix

during routine examination. They are a benign and normal feature of the adult cervix. Nabothian cysts arise from glandular, mucus-producing tissue, and are then superficially covered by squamous epithelium. They are typically raised with a yellow or white appearance and may range from a few millimeters to 3 to 4 centimeters in diameter. Most require no treatment unless excessively large.[55] Women checking for presence of an IUD string may feel a nabothian cyst.

Cervical Ectropion (Ectopy)

Cervical ectopy may cause increased vaginal discharge and, in some cases, postcoital bleeding. While cervical ectopy is normal and is not cervical erosion, women with excessive, symptomatic discharge or postcoital bleeding require further evaluation to rule out abnormalities.

Endocervical Polyps

Endocervical polyps often are an incidental finding during the course of a regular pelvic examination. Their typical appearance is that of a small, red, tongue-like growth protruding from the endocervical canal. An endocervical polyp may frequently be the reason women report postcoital bleeding. The vast majority of polyps in reproductive-age women are benign and do not require removal unless they are a cause of bleeding, though their presence is noted in the woman's record.[55] Malignancy is more likely among perimenopausal and postmenopausal women.

Cervical Lacerations

Parous women may have sustained a cervical laceration during a birth that was not repaired. If the laceration is extensive, it can be a risk for cervical incompetence in a subsequent pregnancy. Cervical lacerations should be noted in the woman's chart and consultation obtained if they are noted during pregnancy or in a woman planning a pregnancy.

Cervicitis

An inflamed cervix typically is accompanied by discharge or bleeding, which may result from either an infectious or noninfectious cause. Presence of discharge that is mucopurulent and associated with bleeding and edema of the cervix requires further evaluation for infection such as gonorrhea. Friability and erosion of the cervix suggest malignancy.

Condylomata Acuminata

Condylomata acuminata (condylomas) are the manifestation of genital infection with HPV. When found on the cervix, condylomas typically appear as bright white growths with a warty or cauliflower-like appearance. They may be seen in the vagina and on the vulva, perineum, or anus as external genital warts. The appearance of condylomas on the cervix will most likely be

accompanied by an abnormal Pap test result. When administered prior to any HPV exposure, the current HPV vaccine will prevent at least 90% of cases of external genital warts. The *Health Promotion Across the Lifespan* chapter provides additional information regarding vaccines, and additional discussion of condylomas can be found in the *Reproductive Tract and Sexually Transmitted Infections* chapter.

Leukoplakia

Leukoplakia is a nonspecific term referring to an area on the cervix appearing as a white, adherent patch of tissue. A midwife can use a cotton-tip applicator to verify if the patch is adherent, which is characteristic of leukoplakia or cervical intraepithelial neoplasm, or not adherent, which is characteristic of candidiasis. Leukoplakia is generally the result of chronic irritation from, for example, the presence of an IUD string. The white color denotes keratin formation over the surface of squamous epithelium. Because it is not possible to distinguish leukoplakia from CIN with the naked eye, further evaluation such as a Pap test always is indicated.

Disorders of the Vulva

Conditions that affect the vulva include cysts, dermatoses, vulvodynia, and other infections.

Bartholin Gland Cysts

Bartholin glands, also called the greater vestibular glands, are two mucus-secreting, nonpalpable, structures located within the vaginal vestibule in the space between the hymenal ring and the labia minora at approximately 4 o'clock and 8 o'clock (**Figure 12-5**). Bartholin glands can develop cysts or abscesses.

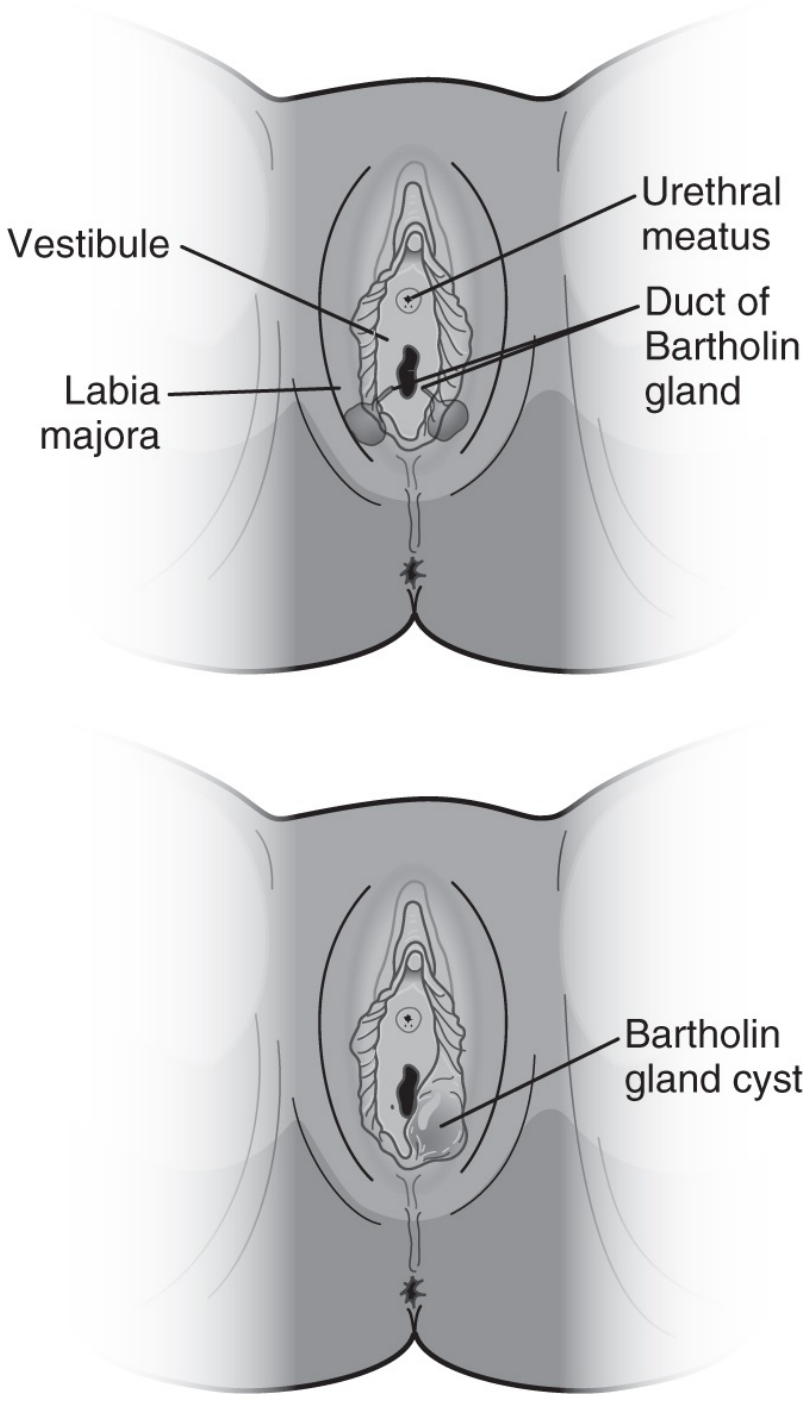

Figure 12-5 Location of Bartholin glands with Bartholin cyst on left side.

Bartholin glands normally secrete a small amount of lubricant. If the gland openings become obstructed, a cyst will develop, resulting in a mass of variable size. Most Bartholin cysts are asymptomatic and do not require treatment. However, if the fluid becomes infected, abscess formation can develop.

Infected Bartholin cysts are usually erythematous and painful. Past literature identified *Neisseria gonorrhoeae* and other STIs as the primary cause of Bartholin abscesses. However, more recent literature reports that the majority of abscesses contain multiple types of bacteria, some of which are part of the normal vaginal flora, including *Escherichia coli*.[56] Methicillin-resistant *Staphylococcus aureus* (MRSA) has been found as the predominant organism in Bartholin abscess in some studies but not all. In general, cysts that exhibit induration, but no evidence of abscess, are treated with a course of antibiotics and warm compresses. Women who are pregnant or otherwise immunocompromised require close follow-up. While the procedure for incision and drainage with placement of a Word catheter is beyond the scope of this text, midwives may add this procedure to their practices following completion of the process described in the *Standards for Practice of Midwifery*.

In 2014, the Infectious Diseases Society of America updated its guidelines for the treatment of skin and soft-tissue infections, classifying Bartholin gland cysts into three categories—mild, moderate, and severe.[57] Mild infections demonstrate only a local, mildly purulent lesion, while moderate infections involve systemic symptoms. A severe infection is one that has failed incision and drainage, has not responded to antibiotic therapy, and shows more significant systemic involvement.[58] Women with recalcitrant or recurrent infections, as well as those requiring surgical intervention, are usually best referred to a specialist.[59]

Human Papillomavirus–Associated Lesions

In addition to causing condylomata on the cervix, infection with HPV can cause condylomata acuminata on the vulva, vagina, perineum, and anus. External genital warts are commonly caused by low-risk HPV types 6 and 11, and are not associated with cancer, but they often cause physical symptoms, carry a social stigma, and lead to multiple costly visits to healthcare providers. The care and treatment of vulvar condylomata acuminata are reviewed in more detail in the *Reproductive Tract and Sexually Transmitted Infections* chapter.

Herpes Simplex Lesions

Within the herpes simplex virus (HSV) family of DNA viruses, eight are associated with human infection. Notably, HSV-1 and HSV-2 can cause both oral and genital infections.

Genital herpes is a chronic, recurrent condition of skin and mucosal surfaces caused by infection with HSV, and is transmitted by sexual contact. The initial infection with HSV typically manifests as painful blisters on the vulva, perineum, vagina, cervix, or anus, although the majority of individuals who carry and transmit genital herpes have never had an outbreak of painful blisters, are asymptomatic, and have not been diagnosed. Although both HSV-1 and HSV-2 can cause genital infection, their clinical course is generally different: Specifically,

HSV-2 causes more genital pain, and outbreaks are typically more frequent. Serologic testing capable of distinguishing HSV-1 versus HSV-2 (or the presence of both) is available. Diagnosis, counseling, and treatment of genital herpes, including its potential effect during the perinatal period, is addressed in the *Reproductive Tract and Sexually Transmitted Infections* chapter.

Dermatologic Disorders

The vulva can develop a variety of benign and cancerous dermatologic conditions. Skin disorders of the vulva may be either chronic or acute. Vulvar disorders can also be a source of sexual pain and dysfunction. Most women with skin disorders of the vulva have itching, pain, or irritation that can be a cause of significant personal distress. Care of women with chronic vulvar conditions can be challenging relative to determining the correct diagnosis, and treatments may or may not be effective. When caring for women with vulvar skin disorders, thorough knowledge of vulvar anatomy and function will guide the evaluation. Skin conditions common in other body sites, such as eczema, psoriasis, and contact dermatitis, frequently appear on the vulva. Vulvar biopsies are the gold standard to differentiate among the various vulvar conditions. Midwives trained in this procedure may incorporate vulvar biopsies in gynecologic practice depending on the practice setting and guidelines.

Folliculitis

Folliculitis of the vulva is a common condition involving hair follicles and sebaceous glands of the vulva. It occurs in hair-bearing areas of the vulva. The typical appearance is that of yellow-white- or red-colored, pinhead-sized pustules with a central hair. Most folliculitis is noninfectious, but secondary skin infections can occur mostly from surface skin bacteria and trauma, such as from shaving, waxing, or use of depilatories. Folliculitis may extend to the buttocks and upper, inner thighs. Treatment consists of avoidance of trauma and treatment with antibiotic creams or ointments.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic skin disease involving a recurrent, inflammatory response in areas where apocrine (sweat) glands reside.[60] Women may also report problems with frequent or recurring boils on their skin. Without a high index of suspicion, an accurate diagnosis may be inadvertently delayed, thereby allowing for progression of disease.

Hidradenitis suppurativa may first appear in adolescence, beginning as painful, nodular lesions or abscesses in the axillary or genital region. When lesions drain, sinus tracts often form, leading to scarring, pain, and deformity in severe cases. In women, the areas most commonly affected by hidradenitis suppurativa are the groin, perineum, and axilla.

Hidradenitis suppurativa is estimated to affect 1% to 4% of the population. While men may also be affected, cases among women outnumber those among men by 3 to 1.[61] The etiology of this disease has not been established, but studies suggest it is a multifocal condition—possibly an inflammatory or immune system disorder involving atrophy of sebaceous or apocrine

glands, which secrete sebum into hair follicles, and produce inflammation leading to hair follicle destruction.[62,63] Smoking and obesity have been associated with severe disease.[63]

No diagnostic testing exists for hidradenitis suppurativa. Depending on the clinical diagnosis and extent of disease, treatment may be topical or systemic. In extreme cases, immunosuppressive therapy, surgical treatments, or laser treatments are recommended. Well-controlled clinical trials have not been published comparing modalities to determine which treatments are most effective, and referral to a specialist is usually the best action.

Lichen Sclerosus

Lichen sclerosus is a common, lifelong, benign condition that can occur at any age, but has two peaks of onset: in prepuberty and during perimenopause and postmenopause.[64] While the cause of lichen sclerosus remains unclear, other conditions with an autoimmune component, such as thyroid disorders, systemic lupus erythematosus, and alopecia, are found among women with lichen sclerosus. Women with lichen sclerosus have itching and pain and may present with dyspareunia. On examination, there may be evidence of scratching and, in severe cases, changes in the appearance of the vulvar skin and loss of architecture. The skin becomes thin with white patches. Once confirmed by biopsy, treatment includes topical steroids and surveillance for signs of vulvar cancer. Referral to an expert in management of vulvar disorders is essential when diagnosis is uncertain or there is limited improvement in the woman's symptoms.

Lichen Planus

Lichen planus is an autoimmune disorder that affects the skin, mucocutaneous sites such as the mouth, the scalp, and the genitalia, most often the vulva or vagina. The etiology is unknown but the disorder is thought to occur secondary to a T-cell–mediated autoimmune response to basal keratinocytes. Like lichen sclerosus, lichen planus primarily affects perimenopausal and postmenopausal women, and is associated with other autoimmune disorders. Symptoms are similar to those of lichen sclerosus, including vulvar soreness, burning, and pruritus.[64] Dyspareunia is common. Vulvar tissue may be more reddened with an erosive appearance and extremely tender to touch.[64] Architectural changes involving the vulva and vagina may be present.

Women may try a number of self-treatments prior to seeking professional care. Once biopsy confirms lichen planus, referral to a provider who specializes in the management of vulvar disorders is advisable, as lichen planus can be refractory to treatment. Lichen planus is associated with a small increase in the woman's risk of vulvar cancer.[64]

Lichen Simplex Chronicus

Lichen simplex chronicus is another vulvar skin condition that can involve the entire perianal region. The most common symptom associated with lichen simplex chronicus is severe itching, leading to a cycle of itch–scratch–itch, with the itching often being severe enough to interrupt

sleep.[64] A thickened and leathery-like skin texture results after long-term scratching, which ultimately damages the protective skin barrier, exposing the woman to secondary infection. Diagnosis is generally based on clinical appearance, as biopsy may be nonspecific. Treatment is directed at reducing the itch–scratch–itch cycle with topical steroids, restoring the normal protective skin barrier, and reducing or managing recurrences.[64]

Complications of Genital Piercing

Though not a disorder, the practice of genital piercing has increased dramatically among all segments of the population. Women may choose genital piercing as a means of personal and sexual expression, and in some cases, it is perceived by women as a form of psychological healing following a traumatic event such as abuse or sexual assault.[65,66] When problems arise as a consequence of piercing, women may initially seek answers from the Internet rather than from their healthcare provider.[67]

Although genital piercing is usually safe when performed by a licensed provider whose practice is regulated by state laws, no national safety guidelines exist. Unless the individual performing the procedure is a licensed health professional, no anesthesia is used when performing piercings.

Health risks of genital piercings include local and systemic infection, scarring, infertility due to infection complications, and urethral scar formation.[65,66] Women considering pregnancy or who are pregnant are recommended to defer genital piercing to avoid risk of blood-borne complications such as hepatitis.[65] The Association of Professional Piercers (listed in the Resources section at the end of this chapter) publishes a quarterly journal on piercing techniques, safety, anthropology, and legislative issues relating to body piercing.

Vulvodynia

Vulvodynia is a chronic genital pain syndrome that is estimated to affect as many as 28% of reproductive-age women during their lifetimes.[58] In 2015, the International Society for the Study of Vulvovaginal Disease (ISSVD), the International Society for the Study of Women's Sexual Health (ISSWSH), and the International Pelvic Pain Society (IPPS) agreed to reexamine and revise terminology related to vulvar pain which now subdivides vulvar pain into one of two categories: vulvar pain that is associated with a specific disorder or vulvodynia which refers to persistent vulvar pain without an identified etiology. The updated terminology appears in **Table 12-8**. The intent of the new terminology was to reflect the complexity of the disease, to distinguish vulvodynia from other pain or infectious syndromes with *known* causes, and to better guide diagnosis and treatment.[68] The current definition of vulvodynia describes vulvar pain that has lasted at least 3 months and has no identifiable etiology.[68]

Table 12-8	2015 Consensus Terminology and Classification of Persistent Vulvar Pain
Vulvar Pain Caused by a Specific Etiology[a]	

Infectious (e.g., recurrent candidiasis, herpes)
Inflammatory (e.g., lichen sclerosus, lichen planus, immunobullous disorders)
Neoplastic (e.g., Paget disease, squamous cell carcinoma)
Neurologic (e.g., postherpetic neuralgia, nerve compression or injury, neuroma)
Trauma (e.g., female genital cutting, obstetric)
Iatrogenic (e.g., postoperative, chemotherapy, radiation)
Hormonal deficiencies (e.g., genitourinary syndrome of menopause [vulvovaginal atrophy], lactational amenorrhea)
Subcategories of Vulvodynia[b]
Localization: localized (e.g., vestibulodynia), generalized, or mixed
Provocation: provoked (e.g., insertional contact), spontaneous or mixed
Onset: Primary or secondary (e.g., symptoms that develop after a period of normal function)
Temporal pattern: intermittent, persistent, constant, immediate, delayed

[a] Women may have both another specific disorder (e.g., lichen sclerosus) and vulvodynia.

[b] Vulvar pain of at least 3 months' duration, without clear identifiable cause, which may have potential associated factors and following descriptors.

Reproduced with permission from Bornstein J, Goldstein AT, Stockdale CK, et al., on behalf of Consensus Vulvar Pain Terminology Committee of the International Society for the Study of Vulvovaginal Disease (ISSVD), International Society for the Study of Women's Sexual Health (ISSWSH), and International Pelvic Pain Society (IPPS). 2015 ISSVD, ISSWSH and IPPS consensus terminology and classification of persistent vulvar pain and vulvodynia. *Obstet Gynecol.* 2016;127:745-751.[68]

The cause of vulvodynia is believed to be multifactorial, and several elements—including pathophysiologic factors, psychological factors, and social and relational factors[69]—may influence either the development or subsequent consequences of this disorder. The presentation of vulvodynia includes symptoms that are either chronic and unrelenting or cyclic in nature which makes the diagnosis of vulvodynia difficult and generally one of exclusion. Various algorithms have been published to aid the clinician in ruling out other potential conditions; **Figure 12-6** shows one example.[69]

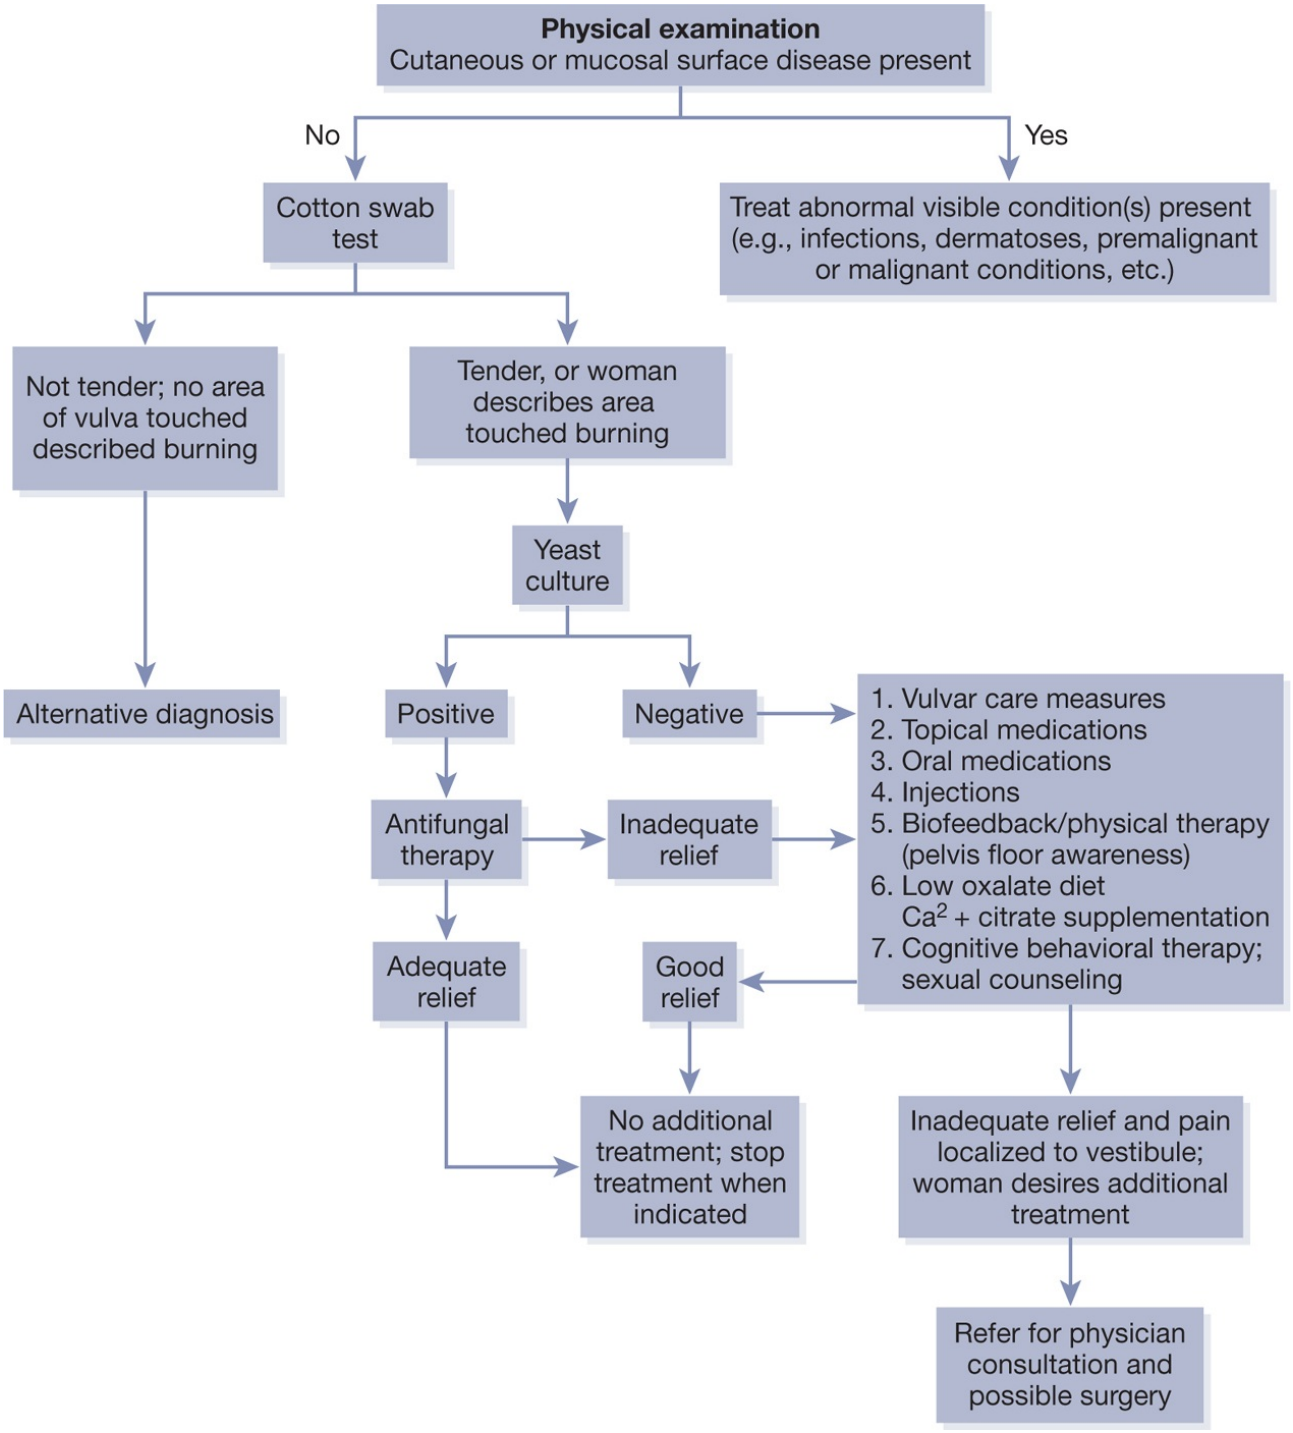

Figure 12-6 Algorithm for the diagnosis and management of vulvodynia.

Modified with permission from Haefner HK, Collins ME, Davis GD, et al. The vulvodynia guideline. *J* **Low Genit Tract Dis**. 2005;9:40-51.[69]

Evaluation of Vulvodynia

The evaluation for vulvodynia starts with a comprehensive history of the onset and duration of symptoms using the OLD CARTS mnemonic (see **Table 12-5**). Other comorbid symptoms, such as interstitial cystitis, fibromyalgia, or irritable bowel, are frequently found among women

with vulvodynia.[70] Physical and sexual abuse in childhood have been identified as possible risk factors for development of vulvodynia.[70]

Examination of the vulva includes evaluation of skin changes, vaginal secretions, presence of lesions, and changes in the vulvar architecture. It is useful to perform an evaluation of point-specific pain and sensitivity using a cotton swab and gently proceeding in a clockwise fashion on the vulva. Particular areas of sensitivity may be noted, especially at the 11 to 1 o'clock points and the 5 to 7 o'clock points (**Figure 12-7**).[71,72]

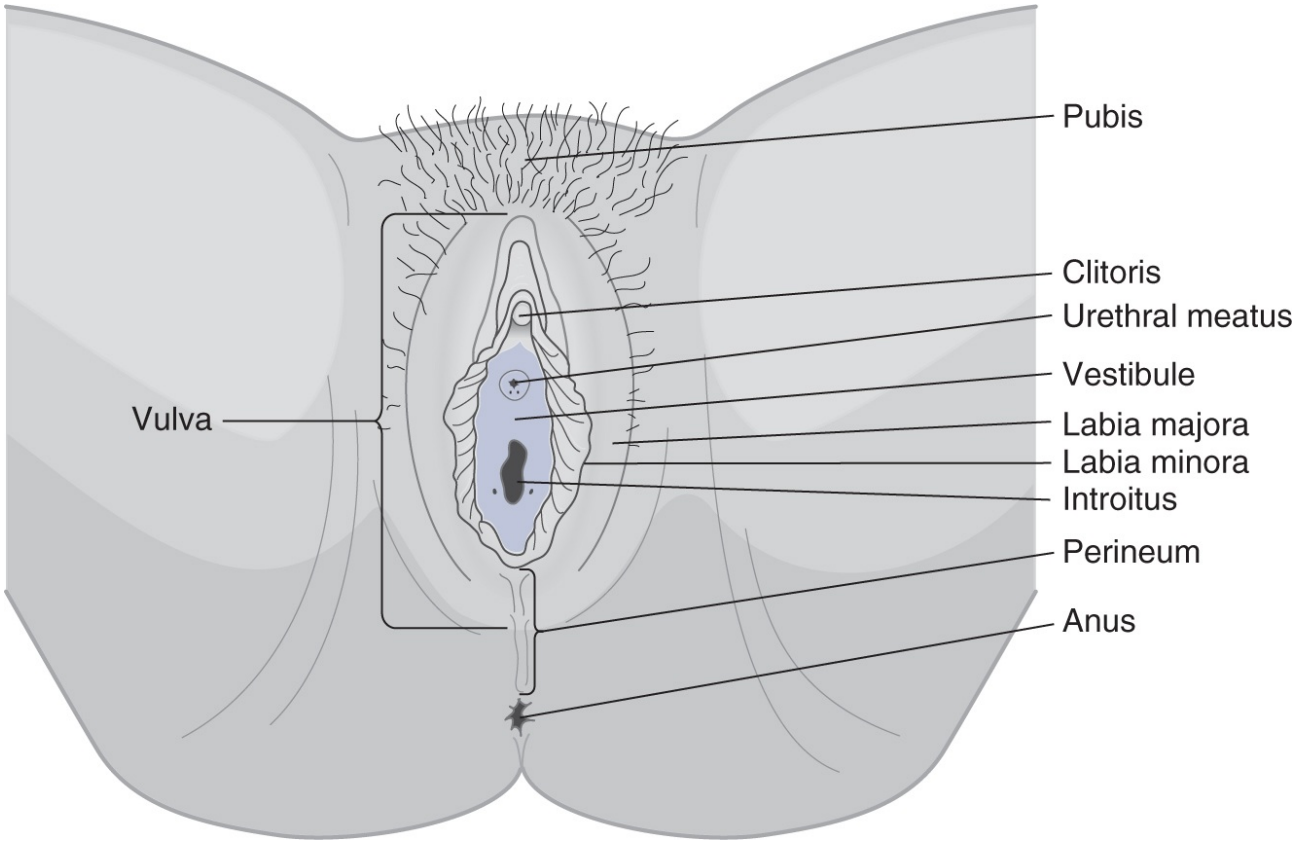

Figure 12-7 Cotton swab test for specific location of vulvodynia.

Treatment of Vulvodynia

Treatments for vulvodynia are wide-ranging in scope, are highly individualized, and usually begin with avoidance of potential irritants. A woman experiencing vulvar pain may have tried numerous over-the-counter treatments, including antifungal and topical steroid preparations. These treatments in themselves may have caused a dermatitis that must be minimized before further evaluation can occur.[71,73] Use of unscented toilet tissue, loose cotton clothing, unscented soaps, and showers instead of baths is recommended.[74] Avoidance of feminine hygiene products, fragranced baths, baby/personal wipes, over-the-counter anti-itch products, detergent additives, fabric softeners, dryer sheets, and latex products has been found to reduce vulvar pain for some women.[71,73,74] Following these initial steps, recommendations for treatment may include psychological interventions, physical therapy, and pelvic floor physical therapy.[74] Antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs) or serotonin–

norepinephrine reuptake inhibitors (SNRIs), also have been used and appear to have some value for relief of pelvic neuropathies.[71,73,74] A variety of alternative or complementary therapies have shown varying degrees of success, including biofeedback, pelvic floor exercises, cognitive group therapy, cognitive-behavioral therapy (CBT), acupuncture, transcutaneous nerve stimulation, and hypnotherapy, although none of these is considered a first-line treatment.[71-74]

When most or all of the aforementioned modalities are unsuccessful, clinicians may recommend surgery, including excision of nerve pathways or nerve injuries associated with specific locations of pain.[75] A pelvic examination presents the perfect opportunity to educate women about care and hygiene practices that protect the vulva, as outlined in **Table 12-9**.[74]

Table 12-9	**Measures to Minimize Vulvar Irritation**
Wear 100% cotton underwear (no underwear at night)	
Avoid vulvar irritants (perfumes, dyes, shampoos, detergents) and douching	
Use mild soaps for bathing, avoiding applying the soap to the vulva	
Clean the vulva only with warm (not hot) water	
Avoid the use of hair dryers on the vulvar area	
Pat the area dry after bathing, and apply a preservative-free emollient (such as vegetable oil or plain petrolatum) topically to maintain moisture in the skin and improve the barrier function	
Switch to 100% cotton menstrual pads as needed (if regular pads are irritating)	
Use adequate lubrication for intercourse	
Consider cool gel packs to the vulvar area	
Rinse and pat the vulva dry after urination	

Modified with permission from American College of Obstetricians and Gynecologists. Committee Opinion No. 673: persistent vulvar pain. *Obstet Gynecol.* 2016;128:e78-e84.[74]

Pelvic Floor Dysfunction Disorders

The two most common findings related to pelvic floor changes are pelvic organ prolapse and urinary incontinence.[76] Both of these conditions can occur secondary to a number of structural abnormalities, physical trauma, or pathophysiologic conditions. Risk factors for both conditions include pregnancy (regardless of the mode of birth), older age, increasing parity, family history, obesity, smoking, constipation, a history of heavy lifting, prior lower abdominal or pelvic surgeries, a lower abdominal or pelvic mass, a history of chronic lung disease, and a history of a connective tissue disorder (e.g., Marfan syndrome).[77-80]

Pelvic Organ Prolapse

Pelvic organ prolapse refers to herniation of pelvic organs to or beyond the vaginal walls. Common forms of pelvic organ prolapse include *cystocele* or *urethrocele* (bladder or urethral descent into the vagina), *rectocele* or *enterocele* (protrusion of the rectum into the vagina), and *uterine prolapse* (descent of the uterus into the vagina); see **Table 12-10**. Each of these conditions, or a combination of them, can cause abnormal bladder or rectal function, pelvic or lower back pain, and/or decreased pleasure with sexual activity.[81]

Table 12-10 Pelvic Organ Prolapse Conditions

Term	Description and Findings
Urethrocele	Prolapse of the urethra, evident as descent of the anterior vaginal wall
Uterine/cervical prolapse	Prolapse of the uterus, evident as descent of the uterus or uterine cervix into the vagina
Vaginal vault (cuff scar) prolapse	Descent of the vaginal vault or cuff scar into the vagina after hysterectomy
Cystocele	Prolapse of the bladder, evident as descent of the anterior vaginal wall
Rectocele	Prolapse of the rectum, evident as descent of the posterior vaginal wall
Enterocele	Hernia of peritoneal sac and small intestine into the rectovaginal space between the vagina and rectum

Although several instruments have been developed to describe the nature and extent of pelvic organ prolapse, the most widely supported is the Pelvic Organ Prolapse Quantification (POP-Q) system, which is endorsed by professional organizations.[82] In using the POP-Q system, the hymen acts as a fixed point of reference and the prolapse is measured with regard to six anatomic locations. The results define one of four stages of prolapse as described in **Table 12-11**.

Table 12-11 Pelvic Organ Prolapse Quantification System (POP-Q)

	Description
Point	

Aa	Anterior vaginal wall 3 cm proximal to the hymen −3 cm to +3 cm
Ba	Most distal portion of the remaining upper anterior vaginal wall −3 cm to +3 cm
C	Most distal edge of the cervix or vaginal cuff scar
D	Posterior fornix (not applicable if posthysterectomy)
Ap	Posterior vaginal wall 3 cm proximal to the hymen −3 cm to +3 cm
Bp	Most distal position of the remaining upper posterior vaginal wall −3 cm to +3 cm
Point POP-Q Staging Criteria	
Stage 0	Aa, Ap, Ba, Bp = −3 cm and C or D ≤ − (total vaginal length − 2) cm
Stage I	Most distal portion of the prolapse −1 cm (above the level of hymen)
Stage II	Most distal portion of the prolapse ≥ −1 cm but ≤ +1 cm (≤ 1 cm above or below the hymen)
Stage III	Most distal portion of the prolapse > +1 cm but < + (total vaginal length − 2) cm (beyond the hymen; protrudes no farther than 2 cm less than the total vaginal length)
Stage IV	Complete eversion; most distal portion of the prolapse ≥ + (total vaginal length − 2) cm

Based on Persu C, Chapple C, Cauni V, Gutue S, Geavlete P. Pelvic organ prolapse quantification system (POP–Q): a new era in pelvic prolapse staging. *J Med Life.* 2011;4:75-81.[82]

Evaluation of Pelvic Floor Disorders

Evaluation of pelvic floor disorders includes obtaining a comprehensive history and visualizing the woman's external genitalia, vagina, and cervix for signs of urinary leakage or organ displacement/prolapse. Asking the woman to perform a Valsalva maneuver or cough allows the midwife to visually assess the level of vaginal wall support. Uterine prolapse may also be observed with the woman in an upright position. In severe cases, the cervix may protrude through the vulva simply by the pull of gravity. A follow-up bimanual examination during which the woman tightens vaginal muscles around the clinician's fingers allows the midwife to gauge the strength of the pelvic muscles, and presents an opportunity to teach the correct method for performing muscle tightening exercises. Two short survey instruments to help clinicians determine the nature and extent of prolapse—the Pelvic Floor Impact Questionnaire and the Pelvic Floor Distress Inventory—are also widely available.

Treatments for Pelvic Floor Disorders

In the absence of pelvic masses, treatment for pelvic floor relaxation may include the initiation of pelvic floor muscle training. While some evidence indicates that pelvic floor muscle training alone can improve pelvic organ prolapse, women often require specific instruction and feedback during a vaginal examination to learn how to perform pelvic floor muscle training correctly, and referral to a physiotherapist specializing in such training may be warranted.[83,84]

A variety of support devices or pessaries can be employed in the case of significant uterine prolapse.[85] In general, there are two types of pessaries (described in **Appendix 12A**) that are used: those that offer support (e.g., ring pessary) and those that fill space in the vagina (e.g., cube pessary). The former are suited for women at POP-Q Stage 1 or 2, while the latter are

designed for women at Stage 3 or 4. After the initial examination and placement of the pessary, the woman returns for a follow-up visit in 1 to 2 weeks to assess comfort and normal urinary function. She then returns again in 3 to 6 months and at least semi-annually thereafter to assess proper use and effectiveness of the pessary. The midwife should teach the woman to remove and clean the pessary weekly with soap and warm water. Women unable to perform self-care should be seen as needed to remove and clean the pessary and ensure proper fitting.[86] Vaginal evaluation includes visual inspection to assess for lesions or bleeding due to tissue erosion caused by pessary use. A woman with a pessary in place should be cautioned to report vaginal bleeding promptly, as this may be a sign of tissue damage or intrauterine bleeding indicative of the growth of a malignancy.

Several surgical procedures have been introduced in an attempt to repair or restore the lost muscle tone associated with pelvic organ prolapse. Despite these efforts, the long-term success rates of different surgical approaches are variable and can result in complications, such as urinary incontinence.[87]

Urinary Incontinence

Urinary incontinence is underreported for many reasons, including personal embarrassment, limited access to health care, and lack of proper screening by clinicians. Underreporting has made it difficult to identify how many women experience urinary incontinence, but reviews of the prevalence, identification, and treatment of urinary incontinence suggest that between 25% and 55% of adult females experience urinary incontinence at some point in their lives. The occurrence can be as high as 75% in older age groups.[88]

Urinary incontinence is often associated with significant diminishment of women's quality of life. Effects of urinary incontinence can include impaired sleep, limitations on the ability to travel far from home or to engage in social activities, and difficulty in maintaining good hygiene to avoid skin irritation or breakdown. The role of the midwife in assessing and treating urinary incontinence is most often accomplished in consultation with colleagues who specialize in urogynecologic care.

Urinary incontinence is classified based on the presenting symptoms and signs, as summarized in **Table 12-12**. The most common types of urinary incontinence are stress, urgency, and overflow incontinence. *Stress urinary incontinence*, which involves involuntary leakage of urine, may co-occur with detrusor overactivity (overactive bladder), defined as involuntary bladder contractions during the filling phase of the bladder. *Urgency urinary incontinence* is less common than stress urinary incontinence; it causes the woman to experience a sudden urge to urinate and subsequent involuntary loss of urine if she is unable to empty her bladder almost immediately. This form of urinary incontinence can be due to a variety of neuropathies. *Overflow urinary incontinence* presents with continuous urine leakage and incomplete bladder emptying. A woman with overflow urinary incontinence may also have frequency, nocturia, hesitancy, and/or a weak intermittent urinary stream. If the bladder is very full, stress leakage may cause symptoms that are similar to those of stress or urgency incontinence. The combination of stress and urgency urinary incontinence is termed *mixed urinary incontinence*.[88,89]

Table 12-12	Types of Urinary Incontinence
Type of Incontinence	**Definition and Description**
Stress urinary incontinence	Involuntary leakage caused by increases in abdominal pressure, effort, or exertion (e.g., sneezing or coughing) but no urge to urinate prior to leakage. Caused by urethral hypermobility, which causes the bladder neck and urethra to lose the ability to close. Can occur secondary to insufficient support from pelvic floor muscles, trauma from childbirth, or chronic pressure from obesity or chronic cough.
Urgency urinary incontinence	Urge to urinate is sudden, with involuntary leakage and frequent small-volume voids. The result of detrusor overactivity. Can occur secondary to bladder abnormalities or neurologic disorders.
Neurogenic detrusor overactivity (overactive bladder)	Involuntary bladder contractions during the filling phase of the bladder, due to a defined neurologic condition. A form of urgency urinary incontinence.
Mixed urinary incontinence	Involuntary leakage associated with both urgency and stress incontinence.
Overflow incontinence	Frequent or constant dribbling or stress incontinence. Typically caused by an underactive detrusor muscle or outlet obstruction. Can occur secondary to detrusor underactivity, which may stem from a low estrogen state, peripheral neuropathy (e.g., diabetes, alcoholism), or spinal cord damage (e.g., muscular sclerosis). Urinary retention can also occur secondary to drug therapy.
Nongenitourinary incontinence	Variable leaking of urine caused by functional problems (e.g., neurologic, psychologic, cognitive), pharmacologic agents, environmental problems, or metabolic disorders.

The need to void once or twice during the night is not necessarily indicative of urinary dysfunction, and an occasional episode of leaking urine does not meet the criteria for incontinence treatment. If the urinary incontinence is a side effect of a pharmaceutical agent, change in mental status, mobility, or new onset of constipation, the condition may be temporary. Increasing age, obesity, smoking, pregnancy, and increased abdominal pressure due to constipation and occupational lifting also have been shown to contribute to urinary incontinence.

Certain disease states are associated with increased urination and incontinence, including diabetes, urinary tract infection or other renal disease, bladder mass, and pelvic masses such as fibroids or ovarian cancer. Surgery or pelvic trauma also can result in involuntary loss of urine. Women who have a vaginal birth do not appear to have a higher risk of urinary incontinence when compared with those having a cesarean birth. A genetic disposition may increase the risk of urinary incontinence even if the woman has never been pregnant.

Evaluation of Urinary Incontinence

In the absence of a urinary tract infection, a pelvic mass, pelvic organ prolapse, or some other extrinsic cause of incontinence, the diagnosis of incontinence is made using a combination of the woman's history and a variety of urinary function tests.

Several clinical assessment instruments are available to aid making a diagnosis of urinary

incontinence, including the shortened versions of the Pelvic Floor Impact Questionnaire and the Pelvic Floor Distress Inventory used to assess pelvic organ prolapse, as well as the often-used Questionnaire for Urinary Incontinence Diagnosis (QUID).[90,91] Women can offer a significant amount of diagnostic information by completing a daily urinary diary that includes the time and amount of oral intake, urine output, any urine leakage, and necessary pad changes. These validated questionnaires are often used to help establish a diagnosis and can be readily obtained from the sites listed in the Resources section at the end of this chapter.[90,91]

Urinary function tests can range from the simple, such as the cough stress test, which can be performed in the office by asking the woman to cough with a full bladder and subsequently observing for leaking from the urethra; to the complex, such as urodynamic testing, which involves the use of equipment that can evaluate urethral function, bladder capacity, bladder stability, and the woman's ability to control voiding. The latter form of assessment can be expensive and is usually reserved as a second line of testing, typically performed by a urologist or urogynecologist.

Treatment of Urinary Incontinence

For women with stress urinary incontinence, initial treatment includes pelvic floor muscle exercises, behavioral modifications, and dietary changes. Weight loss may improve symptoms of stress urinary incontinence.[92] Some clinicians advocate use of Knack exercises, which are similar to Kegel exercises but focus more on strengthening urethral muscles. Knack exercises are a form of Kegel exercise that involves contracting the pelvic muscles as deep into the vagina as possible and holding the contraction while doing other activities during which the woman usually experiences incontinence, such as coughing or exercising in general.[93]

The successful use of pelvic floor muscle training can be enhanced by using provider *feedback* (i.e., giving the woman instructions while performing a bimanual examination) or *biofeedback* (i.e., using a vaginal insertion device that offers feedback on the success of a woman's attempt with the exercises). Similarly, the promotion of healthy dietary changes, especially in women with obesity, may help to reduce incontinence related to obesity.

Pharmaceutical treatments for stress urinary incontinence are generally considered ineffective, and there are no FDA-approved drugs for treatment of stress urinary incontinence.[88] If a woman is diagnosed with stress urinary incontinence combined with urgency or detrusor overactivity (overactive bladder), bladder training is recommended. This training involves either encouraging the woman to delay any initial urges to void by using the Knack technique and simultaneously distracting herself with mental exercises, or teaching her to empty her bladder before an urge occurs.

Two classes of drugs are used to treat urgency urinary incontinence: beta-adrenergic drugs and antimuscarinic agents. Medications approved by the FDA to treat detrusor overactivity are listed in **Table 12-13**.[94-96] Several antimuscarinic agents are available, and they are generally the first-line agents even though they have only modest effectiveness.[95] These drugs increase bladder capacity by blocking muscarinic receptor stimulation by acetylcholine in the bladder during filling. Unfortunately, all these drugs have peripheral anticholinergic effects that limit women's tolerance of them.

Table 12-13 **U.S. Food and Drug Administration–Approved Medications for Treatment of Overactive Bladder**

Medication: Generic (Brand)	Action	Dose	Clinical Considerations
Beta-Agonist Drugs			
Mirabegron (Myribetriq)	Beta-agonist that causes muscle relaxation and increased bladder capacity	25–50 mg per day	Contraindicated for persons with uncontrolled hypertension, liver impairment, or renal disease.
Antimuscarinic Drugs[a]			
Darifenacin (Enablex ER)[a]	Antimuscarinic	7.5–15 mg daily	Metabolized in the liver. Advantages and disadvantages of M3 selectivity are unknown due to the lack of head-to-head trials. Can be taken with food. Half-life is 12 hours.
Oxybutynin (Ditropan IR)[a]	Antimuscarinic Mild antispasmodic Peak action: 1 hour Duration: 6–10 hours	2.5 mg or 5 mg daily, up to 5 mg 4 times a day	Has an active metabolite. Gastrointestinal absorption/liver metabolism leads to increased potential for side effects and drug interactions. Available in liquid formula (5 mg/5 mL). Women with cardiac conditions should take oxybutynin with caution due to its tachycardic side effects. Crosses the blood–brain barrier. Excretion in breast milk is unstudied; lactation suppression has been reported. Use with osteoporosis medications such as alendronate (Fosamax) with caution.

Fesoterodine ER[a] (Toviaz)	Targets M1–M3	4–8 mg once daily	Gastrointestinal absorption/liver metabolism leads to increased potential for side effects and drug interactions. Contraindicated for persons with liver impairment.
Oxybutynin (Ditropan) XL[a]	Antimuscarinic Peak action: 4–6 hours Duration: > 24 hours	5, 10, and 15 mg daily, up to 30 mg daily	Start with 10 mg and titrate; can increase to 30 mg or decrease to 5 mg. Gastrointestinal absorption; similar efficacy and side-effect profile as the immediate-release version. Cannot be chewed or crushed due to the internal dispensing mechanism.
Oxybutynin transdermal (Oxytrol Patch)[a]	Antimuscarinic Steady dose	Change biweekly	Avoids the liver first-pass effect and active metabolite production, which decreases side effects. Discontinuation may occur due to skin site reaction.
Tolterodine IR (Detrol)[a]	Antimuscarinic Peak: 1–3 hours	2 mg twice a day (1 mg and 2 mg tablets)	Gastrointestinal absorption/liver metabolism. Less lipophilic, so it decreases CNS effects, though they have been reported. Pill form only. Start with 4 mg daily, decrease to 2 mg as needed.
Tolterodine (Detrol LA)[a]	Antimuscarinic Peak: 2–6 hours	2–44 mg daily (2 mg and 4 mg tablets)	Gastrointestinal absorption/liver metabolism. Less lipophilic, so it decreases CNS effects, though they have been reported. Pill form only. Start with 4 mg daily, decrease to 2 mg as needed.
Trospium (Sanctura IR)[a]	Antimuscarinic Peak: 4–6 hours	20 mg twice daily	Minimal liver metabolism, with decreased drug–drug interaction possible. Water-soluble, larger molecule allows for possibly decreased crossing of the lipid blood–brain barrier. Cognitive side-effect profile in elderly may be improved, but is not eliminated. Due to water solubility, take on an empty stomach. In elderly, start with one dose daily.
Solifenacin (VESIcare ER)[a]	Antimuscarinic	5–10 mg daily	Metabolized in the liver. Long half-life (approximately 50 hours); no head-to-head comparisons relating to effect. Can be taken with food.

Abbreviations: CNS, central nervous system; ER, extended release; IR, immediate release; LA, long acting; XL, extended release.

[a] All antimuscarinic drugs are contraindicated for persons with myasthenia gravis, gastric retention, and narrow angle-closure glaucoma. In addition, these drugs are associated with a risk for urinary retention, and have side effects of dry mouth, constipation, tachycardia, drowsiness, and decreased cognitive function.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 155: urinary incontinence in women. *Obstet Gynecol.* 2015;126:e66-e81[88]; Sanford M. Mirabegron: a review of its use in patients with overactive bladder syndrome. *Drugs.* 2013;73:1213-1225[94]; O'Dell KK, Labin LC. Common problems of urination in nonpregnant women: causes, current management and prevention strategies. *J Midwifery Womens Health.* 2006;51:159-173.[96]

Injections of botulinum toxin A (Botox A) into the bladder wall also are effective treatments for some women with detrusor overactivity or urgency urinary incontinence. This therapy appears to offer only short-term relief, rendering possible repeat injections necessary for continence to be maintained.[88]

Estrogen was once thought to be a promising treatment for women with urinary incontinence, especially after menopause. While some evidence suggests that topical or vaginal application of estrogen can improve incontinence, oral systemic use of this agent has been associated with worsening symptoms.[88]

Mechanical devices for control of urinary incontinence include vaginal cones and pessaries in various sizes and shapes, which have been used with some reports of effectiveness. Nevertheless, in population studies, their use has not been demonstrated to make a significant difference in bladder control,[97] and they appear to be most effective in conjunction with other treatments, such as pelvic floor muscle exercises and behavioral modifications.

When other treatments have been ineffective, the final approach to treatment of a woman with urinary incontinence is surgery. This approach is limited to stress urinary incontinence, however—it is not applicable to urgency urinary incontinence.[88] Women with stress urinary incontinence considering surgery should be informed of the multiple surgical procedures available and the related side effects associated with each respective approach, and referred to appropriate specialists.

Fertility/Infertility

Infertility is the inability to conceive during 1 year of unprotected, appropriately timed acts of penile–vaginal intercourse or donor insemination.[98] Infertility can be present in a male or female partner. In women, infertility is often associated with, or directly caused by, gynecologic conditions such as uterine anomalies, pelvic masses, or history of pelvic inflammatory disease. Categorizing infertility leads to one of two diagnoses: *primary infertility* for women with no prior pregnancy, and *secondary infertility* for women who have conceived at least once in the past.

While several of the gynecologic conditions discussed in this chapter can contribute to infertility (e.g., endometriosis, uterine fibroids), the cause is often unknown. One-third of the time, infertility is believed to result from conditions affecting the female, one-third of the time from conditions affecting the male, and one-third of the time from conditions affecting a combination of both the female and male. Thus, when discussing infertility with a woman, it is important to consider both partners.[99]

Known biological causes of female infertility include obstruction of the fallopian tubes, endometriosis, pelvic adhesions, hyperprolactinemia, endocrine disorders such as hypothyroidism, and advancing age. Any woman 35 years or older who has been trying to conceive should seek care after 6 months of attempting to become pregnant instead of waiting 1 year.[99] Causes of male infertility are usually secondary to sperm abnormalities, including those related to the quality of sperm and the number of sperm per ejaculation as well as genetic mutations that adversely affect sperm function. The prevalence of chromosomal abnormalities is increased in men with infertility.

Focused History

The initial evaluation for a woman who has been unsuccessful at becoming pregnant begins with a detailed history to ascertain whether the woman's sexual, menstrual, and social history matches the definition of infertility.[99,100] Once it has been determined that a couple's history matches the accepted definition of infertility, a detailed history exploring potential factors related to fertility status should occur. These factors can be related to female anatomy/physiology/psyche, male anatomy/physiology/psyche, or a combination (**Table 12-14**).[99,101]

Table 12-14	Female and Male Factors Associated with Infertility	
History for Both Partners	**Additional Female Medical History**	**Additional Male Medical History**
Current Nature of Intercourse		
Frequency of intercourse Duration of infertility		
Medical History		

History of any prior pregnancies	Prior contraception use	History of varicocele
History of sexually transmitted infections	Dyspareunia	History of mumps
History of genitourinary infection	Abnormal Pap smears or treatment	History of testicular torsion
Symptoms or known diagnosis of endocrine disorders	Pelvic or abdominal surgeries	
Prior chemotherapy or treatments for cancer	Obesity	
Current prescribed or over-the-counter medications	Menstrual history[a]	
History of sexual dysfunction		
Social History		
Smoking, recreational drugs or alcohol use		History or current use of anabolic steroids
Occupational History		
Regular exposure to toxic environmental or chemical substances such as dry-cleaning solvents, pesticides		Regular exposure to high levels of heat (e.g., steel factory workers)
Family History		
Family history of infertility	Family history of early menopause	
Family history of birth defects, developmental delays, cystic fibrosis	Galactorrhea, hirsutism	

[a] Menstrual history includes age of menarche, interval, regular or irregular, amount of flow, history of oligomenorrhea or amenorrhea, and dysmenorrhea.

Based on Koroma L, Stewart L. Infertility: Evaluation and initial management. *J Midwifery Womens Health.* 2012;57:614-621[99]; Lindsay TJ, Vitrikas KR. Evaluation and treatment of infertility. *Am Fam Physician.* 2015;91(5):308-314.[101]

Physical Examination

In addition to assessing vital signs and establishing body mass index (BMI), particular attention should be given to any signs of potential genetic or hormonal abnormalities such as excess androgen. For example, short stature could indicate Turner syndrome [45,XO]; acne, alopecia, or hirsutism should raise suspicion of elevated androgen levels; and galactorrhea could be a sign of hyperprolactinemia. A pelvic examination is performed to assess for conditions related to anatomy (e.g., fibroids, bicornuate uterus), infections (e.g., STIs), and hormonal states (e.g., hypoestrogenic signs, such as a lack of vaginal moisture and a cervix deficient in mucus) that could contribute to infertility.[99,100]

The biological male partner also should be examined, either by the midwife experienced with conducting male examinations, a reproductive specialist, or a urologist. In general, as with the female examination, the clinician looks for signs of anatomic conditions (e.g., enlarged testicular veins causing a varicocele or absent vans deferens), infectious conditions (e.g., prostatitis), and hormonal conditions (e.g., gynecomastia that could be an indication of hyperthyroidism or Klinefelter syndrome [47,XXY]) that can cause infertility.[99,100] Any

suspicious findings, in either the female or the male, indicate a need for referral to a reproductive specialist for further evaluation and care.

The midwife can initiate the assessment for infertility by first reviewing basic sexual knowledge and techniques that optimize the possibility of conception. Topics to review are listed in **Table 12-15**. The midwife can teach the person who is attempting conception to identify signs and symptoms of ovulation using one of the many methods available for this purpose, including charting of daily basal body temperature (BBT), self-evaluation of cervical mucus, ovulation over-the-counter tests, and smartphone apps. Details about using these methods can be found in the *Nonhormonal Contraception* chapter.

Table 12-15 Techniques for Optimizing Natural Fertility

Topic	Content
Timing of intercourse	Intercourse every 1–2 days results in the highest pregnancy rates, but should be based on couple's comfort.
Fertile window	The fertile window varies considerably even in women with regular cycles, but is usually considered to last 6 days. Conception is most likely when intercourse occurs within 3 days before ovulation.
	Three ways of determining the fertile window are available:
	BBT recorded at rest at the same time each day before rising. Fertility is highest 2 days after BBT increases by at least 0.4°F.
	The woman can be taught to self-monitor her cervical mucus. Fertility is highest when the mucus is slippery and clear and intercourse occurs on the day when cervical mucus is most profuse.
	Ovulation detection kits are based on the surge of LH that is associated with ovulation. These kits may underestimate the fertile window, as ovulation can occur up to 2 days after the LH surge.
Coital practices	There is no evidence that coital position improves fertility. Sperm can be found in fallopian tubes within 2 minutes after ejaculation.
	Vaginal lubricants may decrease sperm motility.
Lifestyle considerations	Tobacco and excessive caffeine consumption (> 5 cups of coffee per day) are associated with decreased fertility. The effects of alcohol or marijuana have not been determined.
	Sauna use does not decrease fertility.

Abbreviations: BBT, basal body temperature; LH, luteinizing hormone.

Diagnostic Testing

The initial laboratory testing includes ordering thyroid-stimulating hormone (TSH), free thyroxine (T_4), and prolactin levels for the female desiring conception to rule out thyroid conditions or prolactinemia, which could be associated with infertility. Simultaneously, the male partner may be assessed for thyroid conditions by testing the levels of TSH and T_4, as well as undergo evaluation of testosterone levels for evidence of diminished endocrine production.[99] Male partners initially need a semen analysis to gauge the number, concentration, motility, morphology, form, and structure of sperm per ejaculate. Since conditions associated with biological male partners have been shown to contribute significantly to infertility, and further testing of the female partner can be invasive and costly, an assessment of the male partner's fertility status is conducted early in the process of evaluation for infertility.

Once the basic assessments have been completed, a series of more invasive and expensive procedures are undertaken. Generally, these further steps are conducted under the guidance and care of a reproductive specialist, and can include the use of ultrasonography, magnetic resonance imaging, and laparoscopy.

Treatment of the Woman/Couple with Infertility

A detailed presentation of the treatments available for infertility is beyond the scope of this text. Nevertheless, midwives counseling women and couples diagnosed with infertility should familiarize themselves with the choices available for treatment. These include the use of medications (e.g., clomiphene citrate [Clomid]), surgery (e.g., fimbrioplasty to remove adhesions from fallopian tubes), insemination procedures, and assisted reproductive technologies (ART), such as in vitro fertilization (IVF). Complementary approaches that have been assessed include the use of acupuncture, chiropractic, prayer, antioxidant supplements (e.g., selenium intake to improve the properties of sperm), and psychotherapy, although evidence for the success rates of these approaches is weak and conflicting.[99]

Overall, it is very difficult to predict the success rates of completed pregnancies and live births resulting from treatment for infertility.[101] Many factors contribute to the cause of infertility as well as to the subsequent success of available treatment. Midwives caring for individuals with infertility who are undergoing treatment can provide emotional support in recognition of the physical, emotional, and social pressures that infertile couples face. **Table 12-16** provides a sample of critical elements included in a transfer note after a midwife has performed initial evaluation and determines that more specialized care is needed by a woman/couple with infertility.

Table 12-16 Sample Critical Elements for a Transfer Note for a Woman/Couple with Infertility

Risk factors, if any, that are identified
Current medications
Menstrual history
Past health history of note
Length of time attempting pregnancy (> 1 year if the woman is < 35 years; > 6 months if she is ≥ 35 years)
Care provided: procedures and results for woman/couple; laboratory results or if pending
Summary of rationale for transfer
Request for information about the treatment plan for follow-up

One important aspect with which midwives should be familiar is the prevention of infertility at the outset. Although many causes of infertility involve chromosomal, anatomic, or physiologic factors that are beyond a couple's control, assisting women in leading healthy lifestyles that include safe sex practices, nutritious diets, exercise, and avoidance of smoking or excessive alcohol intake can facilitate desired fertility. Educating clients to avoid exposure to potentially harmful environmental toxins is also important.

Alterations in Women's Sexual Function

Sexuality is an essential component of the assessment of a woman's well-being and gynecologic health. Alterations in women's sexual function may occur with any of the gynecologic conditions described in this chapter, or they may occur independently of them. Women and their healthcare providers often find it difficult to speak about sexuality. The topic can be embarrassing for some, and does not easily fit into a typical 15-minute ambulatory site appointment schedule. Lack of desire may be a major concern for some women, whereas it seems to be a minor consideration or a nonissue for others. Stereotypes abound that can inhibit communication between the provider and the woman and/or between the woman and her sexual partner(s). Even a standard definition of *normal* sexual function is elusive.

Alterations in sexual function are reported more commonly by older persons those with chronic diseases such as cardiac, kidney, and obstructive pulmonary disease, and those who are post cancer treatment.[103-106] Women with endometriosis and infertility are reported to have a higher prevalence of sexual concerns than women in the general population.[107,108] Psychotropic medications, antihypertensive drugs, lipid-lowering agents, and hormones may have negative implications related to sexual function.[109,110]

Sexual Dysfunction Disorders

Four categories of female sexual dysfunction currently are generally accepted among healthcare providers; **Table 12-17** provides an overview of these disorders.[110-113] Regardless of the type or category of disorder, the initial step for assessment includes a thorough history and physical examination. Behavioral counseling is a major intervention for sexual dysfunction disorders since it is considered effective and the presumed harm is low. Other strategies for treatment include mindfulness, as well as creams, gels, and pelvic floor exercises, although the results with these modalities have been inconsistent.[110,111] The vast majority of studies are limited by small numbers of participants, short duration, variation in how alterations in sexual function are defined, and variation in how sexual dysfunction is measured.

Table 12-17 Categories of Female Sexual Dysfunction

Category	Description	Common Management Strategies
Sexual interest/arousal disorder	Includes HSSD, which involves distressing low desire for sexual activity or persistent deficient sexual fantasies. Previously known by the value-laden term of "frigidity," this category also encompasses women who are unable to experience arousal by genital stimulation or nongenital stimulation (e.g., kissing, experiencing erotic situations). Associated with lack of vaginal lubrication. Perimenopausal and postmenopausal women may report secondary arousal problems.	Few studies have found effectiveness of sildenafil (Viagra) in women, but a newer agent, flibanserin (Addyi; 5-HT1a) is FDA approved for this indication. Some evidence of effectiveness for estrogen with or without progesterone therapy has been found for this indication among older women, although the research is not strong.
Substance/medication-	Prominent among the drugs associated with	Changes in types, dose, and other aspects

induced disorder	female sexual problems are antidepressants, especially SSRIs and SNRIs.	of the offending medication are indicated. Determining the optimal antidepressant may take time; care is best managed by a specialist.
Orgasmic disorder	Defined as a persistent or recurrent problem in attaining sexual arousal or the inability to maintain arousal. May be associated with use of antidepressants as well as diseases influencing neurologic health (e.g., diabetes).	Although no FDA-approved drug exists for treating women with this disorder, many providers may prescribe testosterone products on an off-label use with some success. However, type, route, and dose are uncertain.
Genito-pelvic pain disorders	This category includes dyspareunia and vaginismus. Etiology varies, but symptoms often include vestibulodynia, interstitial cystitis, vaginal infections, and vaginal atrophy.	Treatment usually is based on the etiological agent.

Abbreviations: FDA, U.S. Food and Drug Administration; HSSD, hypoactive sexual desire disorder; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective seroton in reuptake inhibitors.

[a] Behavioral counseling is a relatively low-risk intervention that has been used as a treatment modality or in conjunction with other treatments for any woman with a disorder in one of these categories.

Based on Jayne CJ, Heard MJ, Zubair S, Johnson DL. New developments in the treatment of hypoactive sexual desire disorder: a focus on flibanserin. *Int J Womens Health*. 2017;9:171-178[110]; Nastri CO, Lara LA, Ferriani RA, Rosa-e-Silva ACJS, Figueiredo JBP, Martins WP. Hormone therapy for sexual function in perimenopausal and postmenopausal women. *Cochrane Database Syst Rev.* 2013;6:CD009672. doi:10.1002/14651858.CD009672.pub2[111]; Parish SJ, Hahn SR. Hypoactive sexual desire disorder: a review of epidemiology, biopsychology, diagnosis, and treatment. *Sex Med Rev*. 2016;4(2):103-120[112]; Schmidt HM, Hagen M, Kriston L, Soares-Weiser K, Maayan N, Berner MM. Management of sexual dysfunction due to antipsychotic drug therapy. *Cochrane Database Syst Rev.* 2012;11:CD003546. doi:10.1002/14651858.CD003546.pub3.[113]

As female sexuality and alterations in female sexual function become more recognized as an integral component of health, clinicians need research that is robust and meaningful to guide counseling and practice. Healthcare providers who specialize in this area are few in number, but referral is indicated for persons with sexual dysfunction disorders. Midwives may consider additional education and preparation to provide this specialized care so that they can increase women's access to such services and reduce the need for outside referral.

Cancer of the Uterus, Ovary, Vulva, and Vagina

Cervical cancer screening is a well-known primary prevention strategy. By comparison, endometrial cancer is the most common gynecologic cancer in the United States and the second most common gynecologic cancer after cervical cancer in low-resource nations.[114] Perhaps the most troubling of gynecologic cancers is ovarian cancer: It is the second most common gynecologic cancer in the United States but accounts for a greater ratio of deaths per diagnosis than does endometrial cancer or breast cancer.

Cancer of the Uterine Endometrium

While a variety of carcinomas may be found in the uterus, including sarcomas and gestational trophoblastic tumors (e.g., hydatidiform mole), the endometrium is the source of approximately 90% of the cancers involving the corpus of the uterus.[115] When detected early in the disease process, the cure rate for endometrial cancer is high because tumors tend to be localized and well defined. Even so, the incidence of endometrial cancer results in more than 10,000 deaths per year, a mortality rate that, based on the ratio of deaths to new diagnoses (1 to 5.4), is comparable to that of breast cancer (1 to 5.2).[115,116]

Conditions associated with a prolonged exposure to unopposed estrogen are risk factors for development of endometrial cancer. Examples include early menarche or late menopause, polycystic ovary syndrome with anovulation, nulliparity, and use of unopposed estrogens or tamoxifen (Nolvadex). Factors that suggest an underlying prolonged exposure to estrogen may have occurred include unexplained vaginal bleeding in postmenopausal woman, Lynch syndrome, infertility, obesity, and history of breast or ovarian cancer. The most common sign of endometrial cancer, which always requires diagnostic follow-up, is unexplained vaginal bleeding, especially when it is experienced by a postmenopausal woman. Thus, the most widely recommended screening approach for endometrial cancer is education of women about the signs, symptoms, and risk factors associated with the disease.

Endometrial cancer is categorized into two types. Type I, commonly referred to as endometrioid adenocarcinoma, is the most common form, accounting for approximately three-fourths of all cases. Endometrioid adenocarcinoma usually occurs in the perimenopausal years, and if discovered in its early stages, is treatable. Type II, which is unrelated to the presence of estrogen, is less common and has a more dire prognosis than Type I. Some oncologists include a third subclassification, which is hereditary in nature and rarer than Types I and II. The most common cause of this third type of endometrial tumor is Lynch syndrome, which is also called hereditary nonpolyposis colorectal cancer. Lynch syndrome is caused by a genetic mutation that causes the individual to have a high risk for developing colorectal cancer as well as other cancers such as endometrial, ovary, and gastrointestinal cancers.[116]

The first *diagnostic* test for endometrial cancer is endometrial biopsy (EMB), which will reveal normal tissue, hyperplasia, or possibly endometrial cancer depending on the sample obtained. The procedure for performing an endometrial biopsy is presented in the *Endometrial Biopsy* appendix in the *Menstrual Cycle Abnormalities* chapter. Traditionally, the other standard method used for preliminary diagnosis of endometrial cancer has been transvaginal

ultrasound. The most effective method to definitively diagnose endometrial cancer following an EMB or transvaginal ultrasound is to perform hysteroscopy accompanied by a dilatation and curettage (D & C).[116]

For a postmenopausal woman, *any* vaginal bleeding, except that experienced as part of an expected withdrawal bleeding while on hormone therapy, is considered a possible sign of cancer requiring further evaluation. Other signs or symptoms of endometrial cancer, such as pain, usually occur during late-stage disease, when the cancer has spread beyond the uterus.

Other Uterine Cancers

While endometrial cancer is by far the most prevalent form of uterine cancer, two additional forms of abnormal growth are important to note: gestational trophoblastic tumors (e.g., hydatidiform mole) and uterine sarcoma. The most common of these tumors is hydatidiform mole, which consists of abnormal growth of placental tissue. In its beginning stages, this tumor is a benign growth. Women with hydatidiform mole present with a positive pregnancy test, usually with excessively elevated human chorionic gonadotropin (hCG) levels, and abnormal bleeding. The uterus commonly will be found to be larger than expected based on the woman's gestational dates, and confirmation of diagnosis is accomplished through ultrasonography. Treatment most frequently involves the use of suction curettage with the goal of preventing the development of metastatic disease.[117] Additional information on hydatidiform mole can be found in the *Pregnancy-Related Conditions* chapter.

Uterine sarcomas are a rare form of gynecologic cancer (< 1% of these cancers) that account for approximately 3% to 7% of all uterine carcinomas.[118] Generally occurring after menopause, these anomalies originate in the endometrium, the myometrial muscle, or the endometrial stroma. Risk factors include prior therapeutic radiation to the pelvic region. Prolonged use of tamoxifen, and African Caribbean ancestry.[118] There is no recommended form of regular screening, other than the assessment of uterine size and shape that occurs during a gynecologic examination. The most common symptom/sign of this form of cancer is abnormal uterine bleeding. While sarcomas cannot be easily distinguished on physical examination from benign leiomyomas, it is important to remember that sarcomas usually are found in postmenopausal women, whereas uterine fibroids more commonly manifest themselves prior to menopause, and begin to regress in size after menopause when estrogen stimulation diminishes.

If sarcoma is suspected, further assessment may include an endometrial biopsy or a hysteroscopic-guided D & C. However, these diagnostic instruments are less sensitive for sarcomas than they are for endometrial carcinomas. By comparison, more sensitive assessment is achieved with imaging studies, such as computed tomographic scans used to guide needle biopsy or MRI. Employing ultrasound for the diagnosis of sarcoma is not very useful.

Generally, the midwife refers the woman in whom uterine sarcoma is suspected to an appropriate specialist. Prognosis depends on the extent of the disease when diagnosis is made. If the cancer is confined to the uterine corpus at the time of discovery, the 5-year survival rate is 50%, whereas the 5-year survival rate for women with sarcoma that has metastasized ranges from 0% to 20%.[118] Clearly, early discovery is vital to curtailing the spread of this disease—one reason why the significance of uterine bleeding in postmenopausal women should be

stressed.

Ovarian Cancer

Ovarian cancer can occur in epithelial, germ cell, or sex cord stromal cell tissue. The majority of ovarian cancers are epithelial. The 5-year survival rate for women with ovarian cancer is markedly less than that for women with other cancers, primarily because ovarian cancer is often first diagnosed at a late stage. The lifetime risk of being diagnosed with breast cancer is 1 in 8 women whereas the comparable lifetime risk of being diagnosed with ovarian cancer is 1–2 per 100 women.[119] However, this risk varies among different populations. For example, the risk of developing ovarian cancer is greatly increased in women who have a mutation in breast cancer gene 1 (*BRCA1*) or breast cancer gene 2 (*BRCA2*). As with most cancers, the risk of developing ovarian cancer increases with age: It is most prevalent after the age of 45 years; the median age of diagnosis is 63 years.

Known and possible risk factors for ovarian cancer include a history of breast, uterine, or colorectal cancer; postmenopausal status; evidence of mutations in the *BRCA1* or *BRCA2* genes; rarer mutations in more recently discovered genetically based cancers (e.g., the *PTEN* gene associated with Cowden disease that causes a form of thyroid cancer and breast cancer); Lynch syndrome; more than 40 years of active ovulation (e.g., nulliparous never-user of oral contraceptives); early menarche or late menopause; use of infertility drugs for longer than 1 year; and use of unopposed estrogen therapy.[120-123] Notably, repetitive stimulation of the epithelium of the ovary is theorized to result in the development of a malignant state. In contrast, high parity, use of oral contraceptives or injectable depot medroxyprogesterone acetate (DMPA), breastfeeding, hysterectomy and/or salpingectomy, and prophylactic oophorectomy are all associated with a decreased risk of developing ovarian cancer.[121-123]

Bimanual examinations during routine healthcare visits had long been the only screening method for ovarian cancer not dependent on self-report of symptoms, but the sensitivity and specificity of these clinical examinations with regard to detecting ovarian cancer are low. Because a history and physical examination have not been predictive for the detection of ovarian cancer, particularly in its earlier stages, other assessment methods have been suggested as screening mechanisms for this disease. One detection method recommended in the recent past was the presence of increased blood levels of the CA-125 tumor antigen in women with early-onset ovarian cancer. Although CA-125 levels are elevated in women with ovarian cancer, the specificity of this biomarker is limited because elevated CA-125 levels are associated with many other conditions as well. This is an area of ongoing research.

Approximately 10% to 20% of women who develop ovarian cancer have an inherited genetic mutation in *BRCA1* or *BRCA2*. Risk factors that increase the chance of having a *BRCA1* or *BRCA2* mutation are presented in the *Breast Conditions* chapter and reviewed in the *Health Promotion Across the Lifespan* chapter. The term hereditary breast and ovarian cancer syndrome (HBOC) refers to persons who have a family history of multiple cases of breast, ovarian, and/or peritoneal cancers in first-degree relatives. Criteria for offering women screening for HBOC is reviewed in the *Breast Conditions* chapter. Women who are at increased risk for having a *BRCA1* or *BRCA2* mutation should be offered genetic

counseling.[124-127] In short, screening all women for a family history that suggests they are at risk for HBOC and offering those women genetic counseling, which may include testing for *BRCA* mutations, is the current recommendation for ovarian cancer screening.

The lack of evidence regarding the exact etiology of ovarian cancer, definitive risk factors, and means of early detection make screening for this disease difficult for individual women and practitioners alike. Reminders for women about the signs and symptoms of ovarian cancer may potentially aid in detecting this carcinoma. These signs and symptoms include abdominal distension or bloating; flatulence, difficulty eating or easily feeling full when eating, and other persistent gastrointestinal disturbances, including either diarrhea or constipation; abdominal or pelvic pain; fatigue; urinary complaints, including urgency or frequency; and irregular vaginal bleeding.[128]

Cancer of the Vulva and the Vagina

Cancer of the vulva and the vagina account for approximately 6% to 7% of all gynecologic malignancies. The relative 5-year survival rates for vulvar and vaginal cancers are approximately 72% and 49%, respectively.[129,130] The lower survival rate for women with vaginal cancer is in part due to the fact that this malignancy usually presents as a result of metastatic spreading of a cancer whose primary source of development was in another gynecologic organ, such as the vulva or the cervix. When vaginal cancer is discovered prior to spreading beyond the vagina, involving lymph nodes, or metastasizing, the 5-year survival rate is approximately 84%.[131] The vast majority of both forms of cancer are squamous cell in type, and the incidence increases with age.

Both vulvar and vaginal cancer have been increasingly associated with HPV exposure.[132] Consequently, the CDC now emphasizes that receiving the HPV vaccine will protect not only against cervical cancer, but also against vulvar and vaginal cancer. Additionally, any woman with a history of infection with a high-risk HPV type, most likely identified on a Pap test, should be considered at risk for vulvar or vaginal cancer, though the incidence of these cancers is less than the incidence of cervical cancer. Other risk factors for vulvar and vaginal malignancies include smoking, multiple sex partners, other gynecologic cancers, lichen sclerosus, and immunosuppressive disorders (e.g., HIV). A rarer form of vaginal cancer, found primarily in female offspring of women who took DES during pregnancy, is clear cell adenocarcinoma. It first occurs in late adolescence and early twenties, although most of the women affected are now much older and no longer at risk for clear cell adenocarcinoma.[133]

Both screening for and diagnosis of vulvar and vaginal cancers include the identification of any growths in the genital area noted by the woman, or by the midwife during the pelvic examination. The most common site of vulvar cancer is the labia majora, while the most common location of vaginal cancer is the upper third of the vaginal wall.

Early symptoms of vulvar cancer may be persistent pruritus and the presence of condylomata, whereas vaginal disease may be accompanied by bleeding, unusual discharge, and pelvic discomfort. Depending on the extent of the disease process, pelvic examination may reveal a mass at the site of involvement, and possibly lymphadenopathy. Any suspicious lesion should be biopsied, either by a midwife with experience in collecting such samples or by the

specialist to whom the woman has been referred. Referral should occur if any of the following exist: unexplained lymphadenopathy, an HPV lesion that does not improve with topical treatment, or a lesion with an unusual presentation or continued growth over time. As with other gynecologic malignancies, early detection of a vulvar or vaginal cancer can result in a high rate of survival.

Congenital Uterine Anomalies

Congenital uterine anomalies, also referred to as Müllerian anomalies, are present in as many as 10% of all biological females, although the majority of these anomalies are minor.[133-135] These conditions often go undiagnosed until a woman presents for evaluation due to infertility, recurrent miscarriages, pelvic pain, difficulty with vaginal penetrative sexual activity, or ectopic pregnancy.[136] The diagnosis may be made by pelvic examination, by ultrasound, or during a surgical procedure.

During development of the embryo, the two Müllerian ducts differentiate to form the uterus, cervix, superior portion of the vagina, and fallopian tubes. Abnormal development results in a wide range of anatomic malformations. Classification of congenital uterine anomalies has been proposed by the American Society for Reproductive Medicine. Although attempts have been made to update this classification system with more detailed categorizations, the ASRM system remains the standard for describing uterine anomalies and is presented in **Table 12-18**.[136]

Table 12-18 Classification of Congenital Uterine Anomalies

Classification	Description
Class I Hypoplasia or Agenesis	
I A	Vagina (with or without uterine abnormality)
I B	Cervix
I C	Fundus of uterus
I D	Fallopian tube(s)
I E	Combination of above
Class II Unicornuate Uterus (One Single Horn of Uterus)	
II A	Rudimentary horn with endometrial cavity and communicating with single horn of uterus
II B	Rudimentary horn with endometrial cavity but noncommunicating with single horn of uterus
II C	Rudimentary horn without endometrial cavity
II D	No rudimentary horn
Class III Uterus Didelphys	
III	Two separate cavities with two separate cervices
Class IV Bicornuate Uterus	
IV A	Complete: Two separate uterine cavities separated by myometrial tissue and one cervix
IV B	Partial: Septum confined to fundus
Class V Septate Uterus	
V A	Complete: The septum extends into the internal cervical os with two cavities separated by avascular tissue and one cervix
V B	Partial: The septum does not reach the internal os
Class VI Arcuate Uterus	

VI	Concave fundus instead of convex or straight
Class VII Diethylstilbestrol-Related Anomalies	
VII A	T-shaped uterus
VII B	T-shaped uterus with dilated horns
VII C	Uterine hypoplasia

Based on American Fertility Society. The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, Müllerian anomalies and intrauterine adhesions. *Fertil Steril.* 1988;49:944-955.[136]

Normal fertilization may not be possible for women with some Müllerian anomalies, such as agenesis of the fallopian tubes. Other anomalies such as a communicating unicornuate uterus have been found to be associated with endometriosis and dysmenorrhea. However, an arcuate uterus may have no negative impact on conception and pregnancy.

The most recent classification of congenital anomalies by ASRM relates to changes due to the use of DES, a nonsteroidal estrogen that was widely prescribed from 1948 to 1971 in an effort to prevent a number of pregnancy-related complications. Approximately 5 to 10 million pregnant women received DES during this time frame, after which DES was discovered to be not only ineffective but actually harmful to the intrauterine fetus.[133,137] A number of structural and functional abnormalities have been identified as the direct effects of in utero exposure to DES, including changes to the uterus, vagina, and cervix. Reproductive health risks in DES daughters (i.e., biological females exposed to DES in utero) include infertility, ectopic pregnancy, spontaneous abortion, and premature birth. In addition, DES daughters are at greater risk for cervical and uterine carcinomas at age 30 years or younger, and at greater risk for breast cancer at age 40 years and older.[133,137]

To date, the limited data on the outcomes of DES-exposed grandchildren have not demonstrated uterine abnormalities in these individuals. In contrast, animal studies have shown a significant increase in uterine cancers, ovarian tumors, and lymphomas in third-generation offspring of DES-exposed subjects.[133,137] Thus, when obtaining a woman's health history, it is recommended that the midwife inquire whether the woman knows if her mother was exposed to DES, especially if the woman's mother has a history of infertility, difficult pregnancies, or reproductive organ cancers.[138]

Based on the type of anomaly, the contraceptive choices of a woman may be somewhat complicated. The midwife can offer continued support and referral to local resources or national organizations that provide web-based information for women with congenital uterine anomalies. Concerns related to fertility and childbearing are important to reproductive-age women, and should be promptly addressed. Regardless of the woman's age or childbearing plans, information pertaining to an organ anomaly may have a significant emotional impact. Selected resources are listed at the end of this chapter.

Conclusion

The role of the midwife involves care for women across the lifespan. Both historically and currently, that care includes the diagnosis and management of women's gynecologic health. This chapter summarizes some of the more common gynecologic disorders and some additional conditions such as pelvic organ prolapse and alterations in sexual function, and presents the associated diagnostic and management steps. In addition, it provides an overview of gynecologic cancers.

Essential to all midwifery care, for every element of practice, and for every situation, the key to excellent care is listening to the woman and really hearing what she says about her personal symptoms or conditions. Since optimal gynecologic health is a goal for all women, it is essential that the midwife have a working knowledge of the information in this chapter regarding the diagnosis and management of common gynecologic problems, and screening for more complicated conditions. Knowing where and how to access resources and expert care is a lifelong skill for practicing midwives.

Resources

Organization	Description	Webpage
Agency for Healthcare Research and Quality (AHRQ)	Federal agency that publishes multiple guidelines, including guidelines from other groups such as the U.S. Preventive Services Task Force. Among the publications available online are those dealing with cervical screening, management of urinary incontinence, cancer and contraception, and vulvar carcinoma.	https://www.ahrq.gov
American College of Nurse-Midwives (ACNM)	Midwifery organization that includes information about standards and scope of practice as well as a number of position statements. These position statements include *Collaborative Management in Midwifery Practice for Medical, Gynecologic, and Obstetric Conditions* and *Joint Statement of Practice Relations Between Obstetrician-Gynecologists and Certified Nurse-Midwives/Certified Midwives* as well as *Standards for the Practice of Midwifery* that address how to incorporate new procedures into practice.	http://www.midwife.org
American College of Obstetricians and Gynecologists (ACOG)	Organization that issues multiple guidelines and recommendations regarding women's health care. Although large parts of the website are behind a firewall, Committee Opinions and Practice Bulletins can usually be found published in the journal *Obstetrics & Gynecology.* Toolkits on female sexual dysfunction and human papillomavirus vaccinations also are available.	https://www.acog.org
American Society for Reproductive Medicine (ASRM)	Practice guidelines on this website include recommended algorithms for evaluating female and male infertility.	http://www.asrm.org/news-and-publications/practice-committee-documents/
Association of Professional Piercers (APP)	An international nonprofit organization dedicated to the dissemination of vital health and safety information about body piercing to piercers, healthcare professionals, legislators, and the general public.	https://safepiercing.org
Centers for Disease Control and Prevention (CDC)	Consumer-focused page on selected bibliographies related to diethylstilbestrol exposure.	https://www.cdc.gov/des/bibliographies/index.html
National	Federal agency that includes professional	https://www.cancer.gov

Cancer Institute (NCI)	information about a variety of cancers, including cervical, ovarian, peritoneal, vaginal, and vulvar cancer. Clinical databases about research in the area as well as clinical trials are available.	
Our Bodies Ourselves (OBOS)	Provides information about DES exposure, health risks, and other gynecologic conditions.	http://www.ourbodiesourselves.org/health-info/des/
Practicing Physician Education in Geriatrics Project (PPE)	Urinary incontinence toolkit.	http://www.gericareonline.net/tools/eng/urinary/index.html
	These sites have the Questionnaire for female Urinary Incontinence Diagnosis (QUID) and other bladder diary tools as well as professional resources.	http://bronchiectasis.com.au/wp-content/uploads/2015/09/The-Questionnaire-for-female-Urinary-Incontinence-Diagnosis.pdf
Point-of-Care Apps		
American Society for Colposcopy and Cervical Pathology (ASCCP)	Guidelines for management of a woman with an abnormal Pap test. More than a dozen algorithms are included in this site, covering a large number of Pap test results and situations stratified by age and human papillomavirus status, among other factors. A downloadable mobile app is also available from the website.	http://www.asccp.org/Assets/51b17a58-7af9-4667-879a-3ff48472d6dc/635912165077730000/asccp-management-guidelines-august-2014-pdf http://www.asccp.org
International Society for the Study of Vulvovaginal Disease (ISSVD)	Document in outline form describing vulvar lesions by color and shape, to help with diagnosis and treatment. A downloadable app is available for a nominal fee.	https://issvd.org

Fitting a Pessary

KATHRYN OSBORNE

Pelvic organ prolapse (POP) occurs with the descent of one or more of the pelvic organs and resulting herniation of the vaginal wall. This herniation can occur in the anterior vaginal wall (cystocele and urethrocele), the vaginal apex (uterine prolapse), or the posterior vaginal wall (rectocele or enterocele).[1] The most common type of POP is cystocele, which results from descent of the bladder.[1] The peak prevalence of POP is found in women age 60–69 years.[2] An estimated 25% to 50% of women in the United States report some degree of POP.[2,3]

The symptoms of POP differ according to the type of prolapse, but often result in reduced health-related quality of life as a result of bulging in the vagina, sexual dysfunction, and varying degrees of urinary and fecal incontinence.[1] Current recommendations are to consider treatment for women with discomfort associated with vaginal pressure or bulging, sexual dysfunction, or alterations in urinary or defecatory function, and to offer vaginal pessary as a first-line treatment alternative to surgery.[4] Evaluation and management of pelvic organ prolapse is described in the *Gynecologic Disorders* chapter; fitting a ring pessary is described in this appendix.

Types of Pessaries

After a woman and a midwife have engaged in shared decision making and determined that the best approach to treating the woman's pelvic organ prolapse is with a pessary, the first step is to determine which type of pessary to use. Two types of pessaries are available: *space-occupying pessaries* (such as the Gellhorn or cube) and *support pessaries* (such as the ring or ring with support) (**Figure 12A-1).** The choice of pessary type has traditionally been made based on the degree of prolapse; support pessaries have been used to treat Stage I and Stage II prolapse, whereas Stage III and IV prolapse have typically been treated with space-occupying pessaries.[1,5] However, recent research has identified that women with Stage III and IV prolapse can achieve adequate symptom relief with pelvic floor exercises in conjunction with

support pessaries, which are easier for women to remove and replace, and which are associated with less discharge and irritation compared to space-occupying pessaries.[1,5,6] The most commonly used pessary is the ring pessary with support, which is also associated with high rates of symptom relief.[1,5,6]

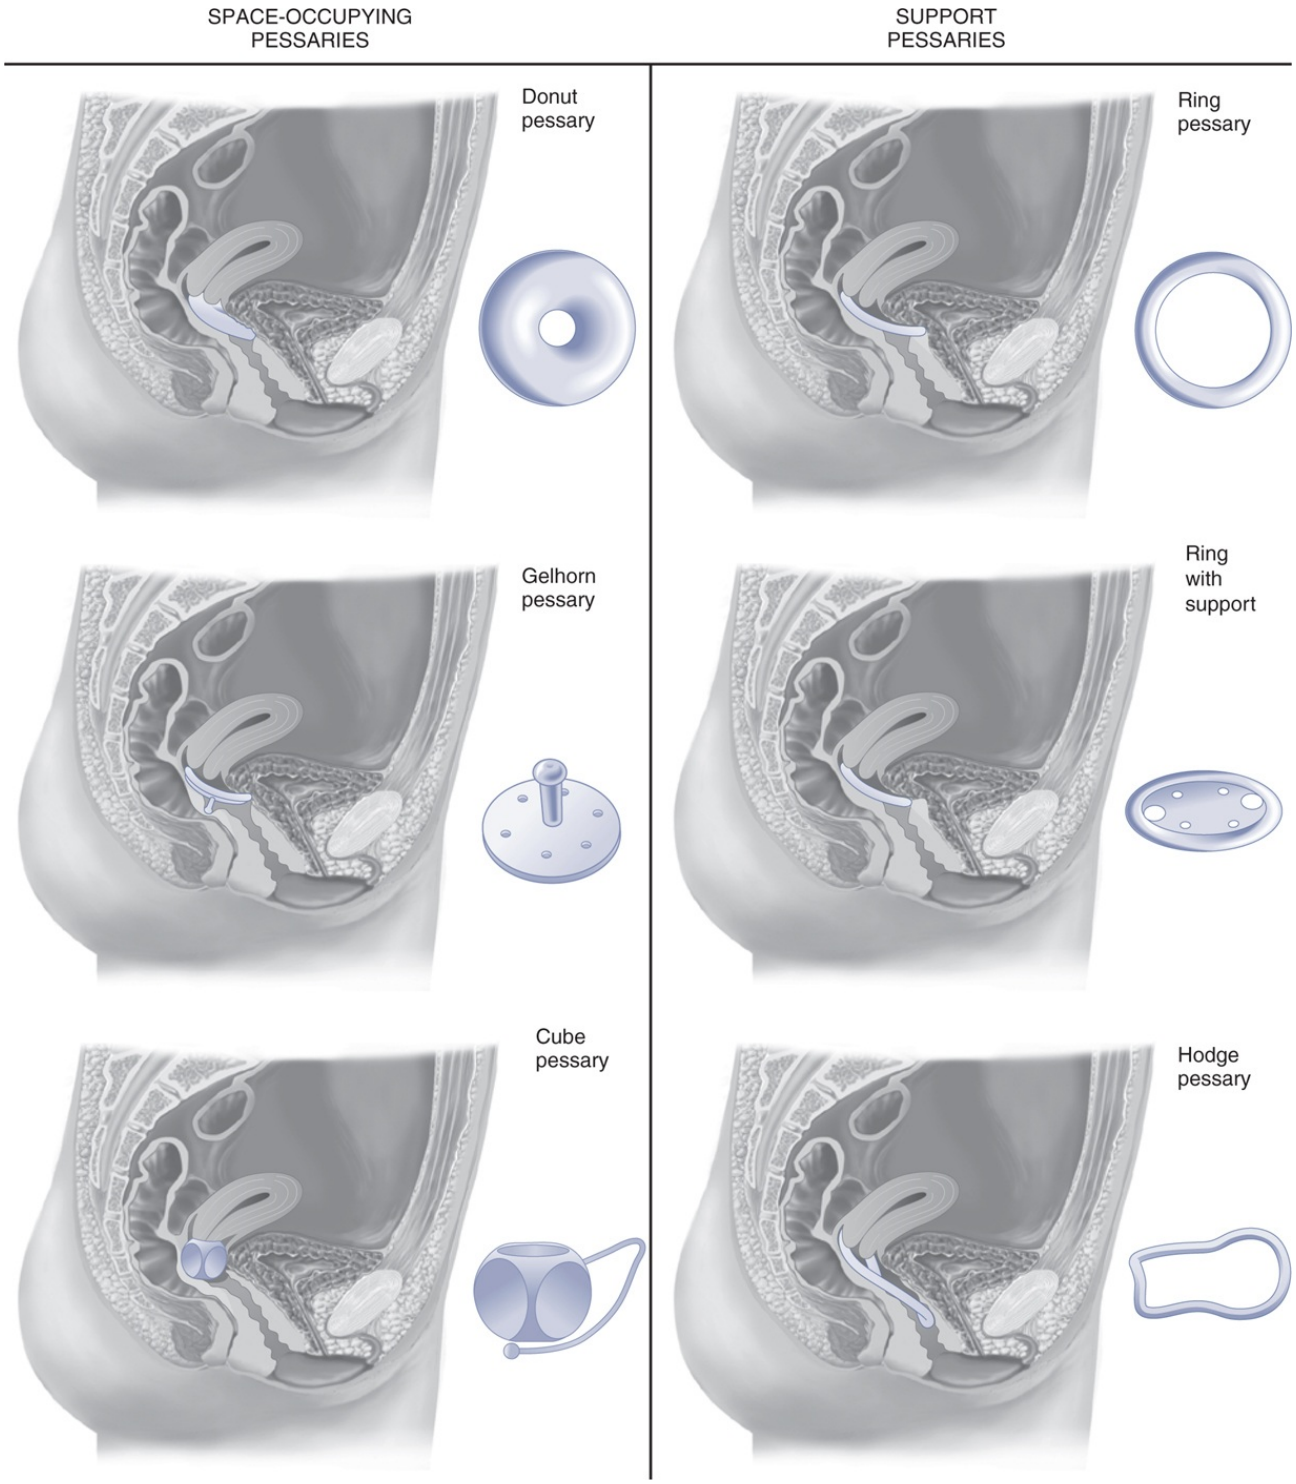

Figure 12A-1 Types of pessaries.

Fitting the Pessary

1. Obtain the necessary supplies: nonsterile gloves, set of fitting rings, and lubricant.
2. Offer the woman an opportunity to empty her bladder.
3. Assist the woman onto an examination table and into the same position used for a pelvic examination; provide draping for privacy and comfort.
4. Inform the woman that you will be conducting a pelvic examination to obtain the internal measurements necessary to fit the pessary, and that she should let you know if at any time she becomes uncomfortable. After obtaining her consent, proceed with the examination.
5. Don gloves. Insert a middle finger and forefinger into the vagina. Place your middle finger behind the cervix in the posterior fornix and place your index finger against the posterior pubic notch. You will use the distance between your index and middle fingers as the initial measurement of the distance between the posterior fornix and the symphysis pubis to size the pessary.
6. Remove your hand and choose the fitting ring with the diameter that most closely approximates the distance between your middle and index fingers.
7. Fold the ring in half and apply lubricant to the end that will be inserted; insert the ring into the vagina so that the ring rests behind the cervix posteriorly and behind the pubic notch anteriorly.
8. Sweep your finger around the diameter of the ring to ensure that the ring is fully unfolded and comfortably in place without undue pressure against the posterior, anterior, or lateral vaginal walls. Ask the woman to bear down and check for movement of the ring as she bears down. If the ring slides over the cervix or is visible at the introitus, repeat this test with a larger ring. A smaller ring will be necessary if the pessary cannot unfold completely or if you are unable to fit your finger between the vaginal wall and the ring; use the largest pessary that retains a comfortable fit.
9. Ask the woman to get up and walk around for several minutes, encourage her to void or defecate if possible. Remove gloves and perform hand hygiene while the woman is moving around.
10. When she returns, assist the woman onto the examination table and reglove. Reassess the placement of the pessary. If it remained in place, remove and discard your gloves before teaching about self-care. Assist the woman to a sitting position.
11. Explain to the woman that she may remove and clean the pessary as often as she feels it is necessary (daily, weekly, or monthly). Also explain that you will offer her an opportunity to practice removing and replacing the pessary before she leaves the clinic.
12. Using a diagram, show the woman how to insert her index finger to locate the pessary (behind the pubic notch) and remove it. Step out of the room and provide her with a private space to remove the pessary.
13. When you return to the room, ask if she felt comfortable removing the pessary and respond to any questions or concerns she may have.
14. Demonstrate how to fold the pessary in half, apply lubricant, and (using a diagram) demonstrate how the pessary is inserted. Explain that placing one foot on the examining table's step stool may make insertion (and removal) easier. Ask if she has any questions

before you leave the room to provide a private space to practice insertion of the pessary.

15. Upon returning to the room, apply gloves and check to see that the fitting ring has been properly replaced. Remove the fitting ring.
16. Remove your gloves, perform hand hygiene, and assist the woman to a sitting position.
17. Provide the woman with cleansing tissue and exit the room so that she may get dressed for the remainder of the visit.
18. Return to the room to discuss any questions or concerns the woman has and review ongoing follow-up.

Ongoing Follow-Up and Management

Women should return to the clinic 1–2 weeks after they begin wearing the pessary to evaluate symptom improvement and satisfaction with the pessary. Most women can safely perform self-care and management of a vaginal pessary, removing and cleaning the pessary with soap and water as often as desired.[1,5,7] Those who perform self-care should return to the clinic every 6–12 months for an examination and assessment of the vaginal wall.[1,5] Women who do not engage in self-care of the pessary should return to the clinic every 3 months to have the pessary removed and cleaned and for an examination of the vaginal wall.[1]

The most common complications associated with pessary use are a malodorous vaginal discharge, vaginal irritation and ulceration, pain, and vaginal bleeding.[1] Most of these complications appear to occur less frequently in women who engage in at least monthly removal and self-care of the pessary.[7] Any woman with an intact uterus who reports vaginal bleeding should be referred for further evaluation. In addition, women who do not achieve adequate symptom relief with a pessary should be referred to a gynecologic or urologic specialist for more extensive evaluation and a discussion of treatment options.

CHAPTER

13

Breast Conditions

JOYCE L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

Culturally, the female breast is often intertwined with the concept of womanhood. Even though the primary function of breasts is lactation, breasts are frequently considered to be erotic and the size and shape subject to sexual description. Conditions of the breast encompass a broad range of pathology, from benign disorders such as fibroadenomas to life-threatening malignancies such as breast cancer. Injury or loss of a breast can be emotionally devastating for a woman.

This chapter reviews normal development of the breast, current recommendations for breast examination, common benign breast disorders, and an overview of breast cancer.

Breast Development

The anatomy and embryonic development of the breast is discussed in detail in the *Anatomy and Physiology of the Female Reproductive System* chapter. The process of development of secondary sexual characteristics takes place in an orderly and predictable sequence. Tanner's classification of sexual maturity is a scale used to evaluate breast and pubic hair growth as a way of assessing normal growth and development. Often the first sign of puberty is thelarche, or the onset of breast development. On average, breast development is initiated at 10 years of age in Caucasian females and 8.9 years of age in African American females.[1]

Both estrogen and progesterone influence the development of the breast, with estrogen stimulating the ductal portion of the glandular system and progesterone stimulating the alveolar or milk-producing components of the system.[2] These two hormones are not sufficient to achieve optimal growth and development; instead, stimulation of insulin, cortisol, thyroxine, prolactin, and insulin-like growth factor is also required. It is not uncommon for the breasts to develop asymmetrically, but usually by the end of puberty the breasts are approximately the same size in most women—although as many as 25% of women have persistent visible breast asymmetry. Significant asymmetry is correctable by surgery; hormone therapy is ineffective for treatment of this condition. The complete development of the alveolus into a mature milk-producing gland is accomplished with the increase in estrogen and progesterone levels that occur during pregnancy.[2]

Breast tissue changes with aging. The adolescent breast has increased density relative to the older breast, as the former consists predominantly of glandular tissue. The breast also undergoes cyclic changes in nonpregnant women due to the influence of estrogen and progesterone. These cyclic changes include increased size of breasts, fluid secretion, and premenstrual tenderness. Breast changes that occur during pregnancy and lactation (i.e., mammogenesis and lactogenesis) are discussed in the *Anatomy and Physiology of Pregnancy* and *Breastfeeding and the Mother–Newborn Dyad* chapters, respectively. In women who breastfeed, glandular tissue regresses and some tissue remodeling occurs once lactation ceases. As women age, breasts become less dense and most women progressively acquire more fat and fibrous connection tissues that gradually replace the glandular tissue.[2]

Gynecomastia, or breast enlargement in males, can be physiologic, may be associated with specific diseases (e.g., Klinefelter syndrome, hyperthyroidism, liver failure), may be a side effect of certain medications (e.g., spironolactone, digoxin), or may result from the decrease in testosterone production as men age. Fifty percent of adolescent males will experience physiologic gynecomastia during early puberty, which usually resolves within 6 months to 2 years after onset. If symptoms persist after 2 years or continue past 17 years of age, further evaluation is needed.[3]

Evaluation of Breast Symptoms

A systematic approach to breast examination is important to evaluate reports of breast concerns. Even though several benign conditions exist, because of the prevalence and fear of breast cancer, the diagnosis of breast cancer should be considered anytime a woman reports any unusual breast symptoms. For providers of care for women, a missed diagnosis of breast cancer can lead to a malpractice claim.

History

The history of presenting symptoms should include the items noted in **Table 13-1**. The healthcare professional should document these components in the record of the woman's visit as positive or negative as appropriate.

Table 13-1 Breast Symptoms That Require Evaluation and Documentation in Health Record

Change in general appearance
Changes over time, especially in relation to menstrual cycle
Skin changes such as thickening of skin (*peau d'orange*), which may indicate inflammatory cancer
Nipple inversion that is a new finding
Nipple discharge: Bilateral or unilateral? Color, timing, frequency, and spontaneous or only if elicited?
Cyclic or noncyclic pain, also known as mastalgia
Masses, including location and changes in size or tenderness with menstrual cycle

The purpose of history taking when evaluating a woman with breast symptoms is both to learn about the symptoms and to assess her risk factors for breast disorders, especially cancer.[4] Although a number of factors have been identified that increase the risk for breast cancer, the majority of women who develop breast cancer (85%) have no identifiable risk other than their gender and their age—both nonmodifiable factors.[3] When evaluating a woman with breast symptoms, factors that increase or decrease her risk for breast cancer should be identified and documented in her health record. **Table 13-2** lists the common risk factors for breast cancer to be reviewed when taking a history.[2,5,6] Factors that are known to be protective against breast cancer include breastfeeding, physical activity, and possibly a Mediterranean diet although it is not clear exactly which components of this diet are the most beneficial.

Table 13-2 Factors That Increase the Risk of Breast Cancer

Risk Factor	Description
Age, gender, race	Advancing age, female, white
Family history	First-degree relative with breast cancer Jewish ancestry Male breast cancer

	First-degree relative with ovarian cancer
	Multiple relatives with cancer, especially hereditary breast and ovarian syndrome–associated cancer (e.g., prostate, pancreatic)
	Known inherited genetic mutations
Health history	Personal history of invasive breast cancer, ductal carcinoma in situ or lobular carcinoma in situ
	Biopsy-confirmed proliferative breast lesions with atypia
	High-dose radiation to chest, usually between years 10 and 30
	Never breastfed
	Previous cancer of the endometrium, ovary, or colon
	High bone density if postmenopausal
	Known inherited genetic mutations
Reproductive history	Early menarche, before age 12 years
	Nulliparity
	Older than 30 years when first gave birth
	Onset of menopause after age 55 years
	Personal or in utero exposure to diethyl stilbestrol (DES)
Medications	Current use of oral contraceptives that contain both estrogen and progesterone
	Hormone therapy with estrogen and progesterone for 5–9 years of use[a]
Lifestyle factors	Alcohol consumption 2–5 drinks per day
	Night shift work
	Physical inactivity
	Smoking
Physical examination	High breast density if postmenopausal
	Postmenopausal obesity

[a] The increased risk of breast cancer is no longer present if there has been more than 5 years since discontinuation of menopausal hormone therapy.

Based on Fritz MA, Speroff L. The breast. In: Fritz MA, Speroff L, eds. *Clinical Gynecologic Endocrinology and Infertility*. 8th ed. Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins; 2011:621-673[2]; U.S. Preventive Services Task Force. Screening for breast cancer: U.S. Preventive Services Task Force Recommendation statement. *Ann Intern Med.* 2016;164(4):279-296[5]; Hoffman B, Schorge J, Bradshaw K, Halvorson LM, Schaffer JL, Corton MM. Breast diseases. In: Hoffman B, Schorge J, Bradshaw K, Halvorson LM, Schaffer JL, Corton MM, eds. *Williams Gynecology*. 3rd ed. New York, NY: McGraw-Hill; 2016:286.[6]

Physical Examination

The clinical examination includes examination of the neck, breasts, chest wall, and axillae. The technique for examination of the breast is detailed in the *Breast Examination* appendix in the *Introduction to the Care of Women* chapter. A full physical examination may also be indicated based on the individual's needs.

Breast findings characteristic of nonmalignant breast disorders include painful or even tender, firm, mobile, well-defined masses that may fluctuate in size and tenderness with menstrual cycle changes. A breast mass is considered a dominant mass if it is a three-dimensional lesion that cannot be replicated in the same location on the other breast. The classic sign of a breast lesion suspicious for breast cancer is a hard, rocky, immobile mass with irregular or ill-defined borders.

Breast masses are to be described as dominant or nondominant and measured in centimeters when possible when noted in the woman's health record. The location, consistency, symmetry, tenderness, and mobility are noted, as are any skin changes. The location may be recorded as distance in centimeters from the areola and by comparing the breast to a clock so that the "o'clock" location can be noted (e.g., a 2 × 3 cm firm, discrete, smooth, mobile, nontender mass 3 cm from the areola at the 4 o'clock position). Negative findings also are to be recorded in a woman's health record. Physical examination cannot distinguish well between malignant and nonmalignant masses, so any palpable mass should be evaluated by the use of the breast assessment modalities discussed next.

Breast Assessment Modalities

Several instruments are available today to assess breast health. Some of these modalities are used for screening women for breast cancers, whereas others are employed for diagnostic indications. **Table 13-3** summarizes these methods, which are discussed in more detail within the subsequent sections on specific disorders, because certain methods are more appropriate than others for some women.

Table 13-3 Common Breast Assessment Methods

Method	Description	Comments
Breast awareness/breast self-examination	A woman's knowledge about her own breasts; may or may not include breast self-examination	General screening for any disorder, most often breast masses Not limited to screening for breast cancer; may discover other disorders Many studies combine with clinical breast examination for research purposes
Clinical breast examination	Examination by a provider as outlined in the *Breast Examination* appendix in the *Introduction to the Care of Women* chapter	An essential component of the physical examination Not limited to screening for breast cancer; may discover other disorders Many studies combine with breast self-examination for research purposes
Mammogram[a]	Standard mammogram uses X rays to assess abnormalities of the breast, including masses, density, and changes in architecture	Regular mammograms are the gold-standard screening technique for breast cancer Also used as part of the diagnostic evaluation indicated when breast masses are palpated
	Digital breast tomosynthesis: a newer type of mammography that provides three-dimensional views	Although FDA approved, in most areas reserved for women at high risk for breast cancer because of cost and specificity issues
Ultrasound	Sonographic assessment of the breast	May be used for screening women with dense breasts (often younger women) at high risk for breast cancer Indicated for women with palpable masses, especially those that are not identifiable on mammograms

Magnetic resonance imaging (MRI)	Method using radio waves and magnetic field to assess the breasts	Primarily used in conjunction with mammography or ultrasound to evaluate extent of cancer of the breast Can be used to screen women at high risk for breast cancer Due to the lack of ionizing radiation, MRI is the preferred method to determine whether silicon implants have ruptured
Biopsy of breast mass	Fine-needle biopsy: a common outpatient procedure to provide cells for cytological study and identification of malignancy Core biopsy, using a larger needle, and open biopsy may be indicated based on size of the mass	Performed by a physician under guided ultrasound or mammogram
	Biopsy at the time of surgery (e.g., lumpectomy, mastectomy)	Most commonly combined with biopsy of nodes Provides staging of cancer

Abbreviation: FDA, U.S. Food and Drug Administration.

[a] Mammography is not infallible; a palpable mass with a normal mammogram indicates the need for referral and additional diagnostic evaluation.

Several algorithms have been developed for evaluation of dominant breast masses.[4,7,8] Some recommend a fine-needle biopsy as the first step, whereas others recommend ultrasound or mammography first. Variations depend on local radiology, pathology, and surgical resources; the woman's age; and her preferences. Ultrasound is generally recommended for women younger than 30 years and diagnostic mammography for women older than 30 years, because the increased density of breast tissue in younger women tends to obscure abnormal findings from mammography.

Table 13-4 lists components that could be included in a note for consultation or transfer of care to a specialist in the area. In this example, the woman has a breast mass.

Table 13-4	Sample Critical Elements for a Consultation or Transfer Note for a Woman with a Breast Mass
Risk factors for breast cancer, including genetics, family history, and personal past history	
Current and past use of hormone therapy, including hormonal contraception	
Discovery of breast mass: by breast self-examination and/or clinical breast examination	
Description of breast mass: location, size, shape, mobility, tenderness, and consistency	
Any breast, nipple, and/or skin changes	
Care provided before transfer: procedures and results; laboratory results or pending status, including pregnancy test, mammogram, and/or ultrasound	
Assessment/diagnosis of the situation	
Summary of rationale for transfer and request for information about the treatment plan for follow-up	

Benign Breast Disorders

Benign breast disorders are a common diagnosis in women's health care and encompass all nonmalignant conditions of the breast, including breast pain (i.e., mastalgia), nipple discharge, and benign breast tumors. Benign breast disorders often are classified as nonproliferative, proliferative without atypia, or atypical hyperplasias. The risk of malignancy is related to the classification. Nonproliferative disorders, which include fibrocystic changes and breast cysts, are not associated with a risk of malignancy. Proliferative without atypia disorders, which include intraductal papillomas, are associated with a modest increase in risk for malignancy. Atypical ductal hyperplasia and atypical lobular hyperplasia are associated with a significant increased risk for malignancy.[7]

Mastalgia

Mastalgia (breast pain) can be either cyclic or noncyclic. Cyclic breast pain generally occurs bilaterally during the luteal phase of the menstrual cycle and resolves after the onset of menses. It is often described as sharp, shooting, or deep aching and throbbing pain. Noncyclic breast pain may be caused by mastitis, cysts, tumors, history of breast surgery, or medications, or it may be idiopathic. Noncyclic mastalgia tends to be localized, subareolar, or medial, and is characterized as tender, burning, stabbing, pulling, or pinching.

Approximately 15% of women with mastalgia require some pain-relieving therapy. Well-fitting bras may relieve some degree of cyclical and noncyclical mastalgia. Flaxseed and Vitex agnus have been evaluated for treatment of women with mastalgia with some positive results.[9] A systematic review suggested that nonsteroidal anti-inflammatory drugs (NSAIDs) were the best first-line treatment for women with mild mastalgia. Vitamin E, 600–3000 units/day, has been associated with improvement with minimal side effects in small studies.[10]

Physician consultation may be indicated for women whose pain is not controlled with NSAIDs. For women with more severe mastalgia, danazol (Danocrine), tamoxifen (Nolvadex), toremifene (Fareston), gonadotropin analogues, and gestrinone (Dimetriose) may be effective, although all have some troublesome adverse effects. Bromocriptine (Parlodel) is no longer U.S. Food and Drug Administration (FDA) approved for the treatment of women with mastalgia due to adverse effects, although it can be used on an off-label basis for this indication. Evening primrose oil has not been found to be effective for mastalgia, and its license for sale has been withdrawn in the United Kingdom due to lack of efficacy.[11] Several randomized trials failed to show any improvements in breast pain with reduction of caffeine, so women should not be counseled to decrease caffeine for this purpose.

Danazol (Danocrine) 100–200 mg/day has been found to relieve breast pain but is associated with significant side effects such as depression, acne, and hirsutism. Low-dose tamoxifen (Nolvadex) at 10 or 20 mg/daily is effective as well, and has fewer side effects than danazol. Low-dose tamoxifen should be considered the drug of first choice if NSAIDs and nonpharmacologic approaches are not sufficient, although this agent is not FDA approved for mastalgia.[2] Tamoxifen is associated with an increased risk of endometrial cancer if taken for longer than 5 years by women who have had breast cancer. This adverse effect does not appear

to be associated with short-term use (≤ 6 months) of tamoxifen.[12]

Nipple Discharge

Nipple discharge is common in reproductive-age women and generally benign, although one retrospective study observed an 11% malignancy rate in women with unilateral single-duct nipple discharge and no abnormalities on imaging.[13] The primary differential diagnosis for nipple discharge is to distinguish benign from pathologic findings. Benign discharge is generally bilateral, multiductal, and milky or green in color, and occurs with breast manipulation.[8,13] Bilateral milky nipple discharge may occur during pregnancy and lactation and may continue for as long as 1 year after childbirth or cessation of breastfeeding. Discharge that is unilateral, clear, serous, or bloody, and occurs spontaneously is more likely to be associated with cancer, especially when it occurs in conjunction with a breast mass and in women who are older than 40 years.[13]

Galactorrhea is defined as bilateral discharge that occurs in women who have not been pregnant or lactating within the last 12 months and is not caused by breast disease. Most often galactorrhea is idiopathic, but it can be associated with prolactin-secreting pituitary adenomas, medications that inhibit dopamine (e.g., some psychotropic medications, combined oral contraceptives, metoclopramide [Reglan], phenothiazines), hypothyroidism, breast stimulation, trauma, and herpes zoster.[2,8,13] More information about pituitary tumors can be found in the *Menstrual Cycle Abnormalities* chapter.

Uniductal, bloody discharge may be associated with intraductal papilloma—a benign tumor of the lactiferous ducts that is generally managed with surgical excision. With unilateral, uniductal, spontaneous, and clear, serous, or bloody discharge, a diagnostic mammogram and ultrasound are indicated and care is usually provided by an expert in the area.[2]

Fibrocystic Changes

Fibrocystic changes (previously called fibrocystic disease) are common and are associated with hormonal stimulation. Thus, fibrocystic changes are rare in postmenopausal women. These changes may be asymptomatic or associated with pain, tenderness, and bumpy areas throughout the breast tissue that fluctuate with the menstrual cycle. Clinical findings include symmetrical nodularity, with nodularity being more prominent in the upper outer region of the breast, and consistency described as like a “bag of beans.” The fibrous tissue may feel firm or rubbery but not rock hard. The cystic portion may feel like grapes.

There is no evidence that fibrocystic changes increase the risk for developing breast cancer.[2,4,7,8] Management options include expectant watchful waiting, aspiration of large or painful cysts, and prescription of combined oral contraceptives to decrease the risk of additional fibrocystic breast changes. Minimal evidence exists to suggest that change in dietary practices, the use of vitamins (e.g., vitamin E) or herbal preparations (e.g., evening primrose), or avoidance of methylxanthines decreases the symptomology associated with fibrocystic changes.

Breast Cysts

Breast cysts are smooth, round or oval, mobile, fluid-filled masses with well-described borders that develop from terminal breast lobules. Breast cysts may be single masses or present as a cluster of multiple small cysts. They may be painful, tender, or painless. These cysts are hormonally influenced and typically appear during menstrual changes in premenopausal or perimenopausal women.

Breast cysts are classified as simple, complex, or complicated based on ultrasonographic evidence of the thickness of the cyst wall and presence of echogenic material within the cyst. Malignancy in simple and complicated cysts is rare, but this risk increases in complex cysts and in cysts that have thickened walls or thick internal septations.[8]

Simple cysts can be diagnosed via ultrasound or fine-needle biopsy that reveals nonbloody fluid and results in disappearance of the cyst. Because the risk of malignancy is very low, a simple cyst generally does not need additional evaluation or follow-up, although it can be aspirated if it is very large or painful. Some experts recommend a follow-up clinical examination or ultrasound in 2 to 4 months to document that the cyst has not changed or recurred after aspiration.

The differential diagnosis for complex and complicated cysts is more extensive and includes abscess, breast cancer, hematoma, fat necrosis, and galactocele. These cysts need a fine-needle biopsy, core biopsy, or excisional biopsy to establish the diagnosis. Care for a woman with breast cysts is best provided by a specialist.

Fibroadenomas

Fibroadenomas are breast masses that most frequently occur in adolescent and young women, although they may be found among women of any age until menopause. These masses tend to be solitary findings, with multiple fibroadenomas noted in only 10% to 15% of women with such masses.[4] On examination, the tumors are nontender, with a firm or rubbery consistency, mobile, and well circumscribed. Mammogram or ultrasound can determine whether the mass is solid or fluid filled (cystic), with the diagnosis then being confirmed through either core needle or open biopsy. Diagnosis on the basis of the clinical examination only is inadequate. If the biopsy indicates that the tumor is a fibroadenoma, it does not need to be removed. The tumor can be followed clinically and removed only if it becomes enlarged or visibly distorts the breast. If the pathology is unclear, the tumor should be surgically excised.[7,8] Fibroadenomas can increase rapidly during pregnancy or estrogen therapy and may regress after menopause. They are not associated with an increased risk of breast cancer.[2,4,7,8]

Atypical Hyperplasia and Lobular Carcinoma In Situ

Atypical hyperplasia includes atypical ductal hyperplasia and atypical lobular hyperplasia. Both are often incidental findings from a core-needle biopsy that is performed as part of the evaluation of another breast mass. Atypical hyperplasia is a pathologic diagnosis that describes abnormal cells of the breast that are associated with an increased risk of breast cancer. This condition is generally treated with surgery (e.g., wide-excision biopsy or

lumpectomy) to remove all the affected tissue. More frequent screening for breast cancer (e.g., mammograms) and strategies to reduce breast cancer risk (e.g., preventive medications such as tamoxifen [Nolvadex], raloxifene [Evista], or anastrozole [Arimidex] as found in **Table 13-5**) may be recommended as well.[7]

Table 13-5 Selected Adjuvant/Preventive Therapies for Atypical Hyperplasia

Agent Generic (Brand)	Route	Side Effects and Toxicities
Antiestrogens		
Tamoxifen (Nolvadex)	Oral	The most common side effects are hot flashes, fluid retention, vaginal discharge, nausea, vomiting, and irregular vaginal bleeding. Increased risk of thromboembolic events (e.g., deep vein thrombosis, pulmonary embolism, and stroke) also exists. Tamoxifen acts as an estrogen agonist in the uterus, increasing the risk for endometrial cancer.
Raloxifene (Evista)	Oral	Side effects are similar to those for tamoxifen, although raloxifene does not increase the risk for endometrial cancer.
Aromatase inhibitors		These drugs have a low incidence of serious short-term side effects. They are not associated with an increased risk of endometrial cancer or thromboembolism.
Anastrozole (Arimidex)	Oral	The most common side effects are hot flashes, vaginal dryness, musculoskeletal pain, and headache, but they are usually mild.
Letrozole (Femara)	Oral	The most common side effects are musculoskeletal pain and nausea.
Exemestane (Aromasin)	Oral	The most common side effects are fatigue, nausea, hot flashes, depression, and weight gain.
Monoclonal Antibody		
Trastuzumab (Herceptin)	Intravenous	The major concern with this drug is cardiac damage that can lead to ventricular dysfunction and congestive heart failure. Many individuals experience flu-like symptoms during the first infusion. Infrequently, women may have a serious hypersensitivity reaction. Trastuzumab does not cause bone marrow suppression or hair loss.

Lobular carcinoma in situ (LCIS) is an area of abnormal cell growth. LCIS is a histologic diagnosis and the disorder is associated with an increased risk for breast cancer, both in the affected breast and the contralateral breast. There are no breast masses associated with LCIS. Because LCIS is not a precursor lesion for breast cancer, complete excision is not indicated. Although the name of this condition includes “carcinoma,” LCIS is not a true breast cancer. To decrease the potential for confusion, some oncologists prefer to use the term “lobular neoplasia” to describe this finding. Increased surveillance for breast cancer and risk-reduction medication should be strongly recommended when a woman is diagnosed with LCIS.[7]

Breast Cancer

Cancer may develop in any of the tissues present in the breast including epithelial, muscle, connective tissue, or fat. The majority of breast cancers are carcinomas that appear in the epithelial cells that line other tissues. Breast carcinomas are categorized as invasive (infiltrating) or non-invasive (in situ). There are several histologic subtypes of invasive breast carcinomas. Non-invasive breast carcinomas are either ductal or lobular.

Worldwide, breast cancer is the most commonly diagnosed cancer and a leading cause of death among women age 40 to 55 years in the United States. African American women have a lower incidence of breast cancer but a higher mortality rate compared to white women.[14] The causes of this striking racial disparity are complicated and include many clinical and non-clinical factors. For example, breast cancer is more biologically aggressive in African American women. Biologic factors in combination with social inequities such as less access to care may partially explain the racial disparity in breast cancer mortality. The clinical implication of this paradox is that social inequities are modifiable when they are identified.

Women have approximately a 1 in 8 chance of developing breast cancer over the course of their lifetime.[15] The risk of developing breast cancer increases as one ages. Conversely, mortality rates have decreased. Between 1989 and 2012, death rates due to breast cancer have declined by 36% overall—a trend attributed to earlier detection, improved treatment modalities, and decreasing use of hormonal replacement therapy.

Factors That Affect Breast Cancer Risk

Several personal characteristics that increase or decrease one's risk for breast cancer have been identified as noted in **Table 13-2**. For example, breastfeeding decreases a woman's risk for subsequent breast cancer whereas alcohol abuse increases the risk for breast cancer. The National Cancer Institute provides a tool on its website that calculates an individual woman's risk of developing breast cancer (see the Resources section at the end of this chapter). The variables that are used to calculate this risk include a history of ductal carcinoma in situ or lobular carcinoma in situ, presence of *BRCA1* or *BRCA2* gene mutations, current age, age at menarche, age at first live birth, number of previous breast biopsies, number of first-degree relatives with breast cancer, and the woman's race/ethnicity.[16,17] This interactive program is based on the Gail model, the most commonly accepted program to calculate risk. Other models have been suggested, though none is infallible for forecasting purposes; nevertheless, they provide a framework for identifying women at risk.[17]

A meta-analysis of prospective studies regarding soy isoflavones consumption and risk of breast cancer suggests that soy isoflavones intake is associated with a significant reduction in the risk of breast cancer in Asian populations, but not in Western populations—although further studies are needed to confirm this finding.[18] Other factors that may be associated with lowering the risk of breast cancer include breastfeeding,[19] 3 to 5 hours of moderate to vigorous physical exercise per week,[20,21] limiting alcohol intake,[22,23] and maintaining a healthy body weight.[24-26]

Hereditary Breast and Ovarian Cancer Syndrome

Although most women with breast cancer do not have a family history of the disease, approximately 5% to 10% have inherited gene mutations that place them at increased risk for developing this disease. Hereditary breast and ovarian cancer syndrome (HBOC) refers to an inherited risk for female and male breast cancer. HBOC may be present in persons who have multiple cases of breast, ovarian, pancreatic, or prostate cancer within a family. The majority of persons with HBOC have mutations in the breast cancer susceptibility gene 1 (*BRCA1*), which is located on chromosome 17q21.3 or breast cancer susceptibility gene 2 (*BRCA2*), which is located on chromosome 13q12-13. These are genes that are associated with tumor suppression.

The prevalence of *BRCA1* or *BRCA2* varies. In the general population, the prevalence is approximately 1 in every 300 to 800 persons whereas approximately 1 in 40 individuals who are of Ashkenazi Jewish background carry the mutation. Mutations of these genes are inherited in an autosomal dominant pattern and therefore offspring have a 50% chance of being a mutation carrier.

When one of these gene mutations is present, the risk for developing breast and/or ovarian cancer is greatly increased. Overall, approximately 4.5% of breast cancer cases occur in women with a genetic mutation and 80% of those are *BRCA1* or *BRCA2*.[27] The cumulative lifetime risk of developing breast or ovarian cancer in women with *BRCA1* is approximately 72% and 44%, respectively. For women with *BRCA2* mutation, the risk of developing breast and ovarian cancer is approximately 69% and 17%, respectively.[27] BRCA mutations are also associated with an increased risk for pancreatic cancer and melanoma.

Screening for Hereditary Breast and Ovarian Cancer Syndrome

It is recommended that all women be screened for possible inherited cancer gene mutations and if risk factors are present (**Table 13-6**) they should receive genetic counseling and be offered genetic testing.[28-30] Knowing her genetic status may allow the woman to seek out preventive measures such as prophylactic removal of the breasts and/or ovaries or the use of medications to lower her risk for breast cancer. Several screening tools approved by the U.S. Preventive Services Task Force are listed in the Resources section at the end of this chapter.

Table 13-6 **Risk Factors for Hereditary Breast and Ovarian Cancer Syndrome**

Woman's Medical History
Breast cancer diagnosis at ≤ 45 years (female)
Breast cancer at any age and Ashkenazi Jewish ancestry
Breast cancer and close relative[a] with breast cancer that developed at age ≤ 50 years or close relative with epithelial ovarian, tubal, or peritoneal cancer at any age.
Breast cancer diagnosis with two or more close relatives[a] with breast cancer at any age
Breast cancer diagnosis at ≤ 50 years with limited or unknown family history
Triple-negative breast cancer diagnosed at ≤ 60 years

Two or more primary breast cancers with first diagnosed ≤ 50 years
Epithelial ovarian, tubal, or peritoneal cancer
Pancreatic cancer and two or more close relatives[a] with breast, ovarian, tubal or peritoneal, pancreatic or aggressive prostate cancer
Family History
Close relative who meets any of the above criteria
Close relative known carrier for *BRCA1* or *BRCA2*
Close relative[a] with male breast cancer

[a] Close relative refers to first, second, or third degree relative.

Data from American College of Obstetricians and Gynecologists. Practice Bulletin No. 182: hereditary breast and ovarian cancer syndrome. *Obstet Gynecol*. 2017;130e110-130e116[28]; Smith EC. An overview of hereditary breast and ovarian cancer syndrome. *J Midwifery Womens Health*. 2012;57:577-584[29]; Moyer VA, on behalf of the U.S. Preventive Services Task Force. Risk assessment, genetic counseling, and genetic testing for BRCA-related cancer in women: U.S. Preventive Services Task Force Recommendation Statement. *Ann Intern Med*. 2014;160:271-281.[30]

Women who are BRCA mutation carriers should practice self-breast examination monthly; receive a clinical breast examination, mammography, and breast MRI annually, and be evaluated with a pelvic examination, transvaginal ultrasound, and test for CA-125 every 6 months.[29]

Screening for Women at Low or Average Risk for Breast Cancer

Multiple low- and high-technological interventions have been used over the years for screening asymptomatic, low-risk women as well as for diagnostic purposes, especially when a breast mass is identified by a clinician. In recent years, widespread use of breast cancer screening modalities as well as advances in treatment have significantly reduced mortality due to breast cancer. A systematic review of randomized clinical trials, and observational and modeling studies published after January 1, 2000, demonstrated that for women of all ages at average risk, screening reduced breast cancer mortality by approximately 20%.[31]

Regular breast screening for cancer has become standard practice in much of the United States. Nevertheless, controversies regarding the best type of screening and the ideal frequency of screening persist. Organizations focused on cancer prevention, such as the American Cancer Society, tend to advocate more frequent screening. In contrast, other population-based groups, such as the U.S. Preventive Services Task Force, have published guidelines urging later initiation of screening and less frequent screening. Although all the groups have access to the same evidence, interpretation of that evidence depends to some degree on the lens through which the organization views it.

Breast Self-Examination for Screening

Traditionally, after menarche all women have been encouraged to perform monthly breast self-examination (BSE) as an instrument for early diagnosis of cancerous tumors and, therefore, as a means to ensure early treatment and decrease the mortality associated with breast cancer. Controversy now surrounds the recommendations regarding BSE, as several randomized trials conducted in the 1990s found no reduction in breast cancer mortality in women who practiced monthly BSE.

Not all of the research agreed on this point, particularly because some studies used differing methodologies and populations. For example, a retrospective study published in 2012 by the Mayo Clinic, reported that while the majority of women with breast cancer presented with image-detected breast cancer, 36% of women presented with palpable disease that was found on either BSE or clinical breast examination (CBE). Those with palpable disease tended to present symptomatically between screening mammograms. Such women also tended to be younger and have more aggressive tumor characteristics (e.g., larger tumor size, axillary node involvement, high grade, and estrogen receptor–negative tumors) compared to women whose tumors are detected via mammogram. The researchers concluded that BSE and CBE can remain important components in breast cancer diagnosis.[32]

With regard to women at high risk for breast cancer, a prospective study reported that 43% of new breast cancers were detected by BSE in 147 women who were at high risk for breast cancer and undergoing intensive breast cancer screening (e.g., yearly mammograms and yearly magnetic resonance imaging), and who are more likely to present with screening-interval cancers.[33] These studies suggested that BSE can be an important surveillance tool especially for women who have a high risk for developing breast cancer and that BSE education should

be a component of the follow-up of this population.[33,34]

Today, several organizations, including the Canadian Task Force on Preventive Health Care, the U.S. Preventive Services Task Force, and the World Health Organization, recommend against teaching women how to perform BSE. This recommendation is based on research that found BSE may actually be harmful because it increases both the number of imaging procedures and the number of breast biopsies without a concomitant decrease in mortality.[28] The American Cancer Society no longer recommends monthly BSE, but does state that BSE can be an option for women older than 20 years. The American Cancer Society recommends that women should be told about the benefits, limitations, and potential harms (the possibility of a false-positive result) of this examination technique.[35]

Currently, "breast awareness" is recommended in place of BSE. No standard definition exists for breast awareness, but the general consensus is that women can be taught to be aware of the normal shape and consistency of their breasts. Any changes in how their breasts feel or look should be an impetus for a visit with a healthcare provider. Women who have breast implants should likely include regular BSE in their plan for breast awareness.

For those women who perform BSE, the technique that is recognized by the American Cancer Society includes both inspection and palpation using the vertical stripe technique described in the *Breast Examination* appendix in the *Introduction to the Care of Women* chapter. Some evidence indicates that the up-and-down pattern of examining the breast decreases the likelihood that breast tissue will be missed.[34]

Clinical Breast Examination

Regular examination of the breasts by a healthcare professional also has been recommended as an important part of breast cancer screening, although there have been no randomized trials that evaluated the benefits of clinical breast examination as a sole screening modality. The Canadian National Breast Screening Study compared CBE and BSE plus mammography to CBE alone in women between 40 and 49 years and between 50 and 59 years. CBE was performed by healthcare professionals who were trained in the techniques of CBE and who also had periodic evaluations of performance quality. The frequency of cancer diagnosis, stage at diagnosis, and breast cancer mortality rates 11 to 16 years after entry into the study were similar in the two groups.[36] For women who were high risk for breast cancer based on a positive family history of breast cancer, another study reported that after a normal initial evaluation, women using BSE and/or CBE found more cancers than mammography.[37]

Several studies have noted that the CBE technique may influence the accuracy of the examination. Miller et al., in a review of the literature, found that poorly performed CBE (e.g., clinicians who fail to use a systematic search pattern) is widely prevalent.[36] A recent observational study noted that using a rubbing movement (defined as repetitive movements in a circular motion or pushing the fingers back and forth or right to left in a repetitive motion) was four times more likely to yield an accurate assessment compared to vertical movement (defined as pushing the fingertips or pads into and out of the breast tissue in a repetitive motion) or piano fingers (defined as the use of individual fingers, in series, to "march" across the breast tissue in a repetitive fashion).[38] When firm pressure is used, breast masses are more likely to

be identified.[39]

Mammography

Mammography, which uses X rays to image breast tissue, can be done as either a screening modality or a diagnostic test. A standard screening mammogram involves four images that are evaluated for changes suspicious of cancer, microcalcifications (a benign finding), distortions of the normal architecture of the breast, and nonpalpable lesions. A diagnostic mammogram is used to further examine areas of concern that are seen on the screening mammogram. Mammography can often detect early-stage breast cancers for which treatment may be more effective, with a subsequent increased likelihood of a cure. Numerous studies have shown that routine mammography may reduce breast cancer mortality by 30% overall and by 20% in women age 40 to 49 years.[40] Mammography can detect an estimated 80% to 90% of breast cancers in asymptomatic women.[40] Similar to research about BSE and CBE, some controversies exist, especially regarding the use of routine screening.

A Cochrane systematic review published in 2013 evaluated seven randomized trials that compared women screened by mammograms with women who were not screened using this technique. The trials included 600,000 women age 39 to 74 years. The three trials with adequate randomization failed to find a statistically significant reduction in breast cancer mortality at 13 years. The other four trials, all of which had suboptimal randomization, demonstrated approximately a 25% reduction in breast cancer mortality at the same time point (relative risk [RR], 0.75; 95% confidence interval [CI], 0.67–0.83). In their analysis, the authors noted that if one assumes mammograms lead to an overdiagnosis and overtreatment rate of 30% and a reduction of breast cancer mortality by 15%, then for every 2000 women screened over 10 years, 1 will avoid death from breast cancer and 10 will be treated unnecessarily. The women in the false-positive group may undergo unnecessary lumpectomies and mastectomies. Of the women who receive a false-positive result, the psychological distress may last for years and the cost is difficult to assess. Based on these results, the researchers did not recommend discontinuation of mammography, but strongly suggested that women be fully informed before entering into routine screening.[41]

Abnormal Mammogram

Mammographic findings are reported using the Breast Imaging Reporting and Data System (BI-RADS), as described in **Table 13-7**. Based on these findings, further imaging studies or a tissue diagnosis may be indicated.

Table 13-7	Breast Imaging Reporting and Data System Classification
BI-RADS Assessment Category	**Likelihood of Cancer**
Category 0: Incomplete—need additional imaging evaluation	
Category 1: Negative	Essentially 0% likelihood of malignancy

Category 2: Benign	Essentially 0% likelihood of malignancy (may be affected by breast density)
Category 3: Probably benign	> 0% but ≤ 2% likelihood of malignancy
Category 4: Suspicious	> 2% but 95% likelihood of malignancy
Category 5: Highly suggestive of malignancy	≥ 95% likelihood of malignancy

Abbreviation: BI-RADS, Breast Imaging Reporting and Data System.

Initiation and Frequency of Mammography

Debate exists particularly regarding the point at which to initiate mammography screening, the frequency of such screening, and the age at which it can be discontinued for women who are not at high risk for breast cancer (**Table 13-8**).*5,42-46* Studies have indicated that the sensitivity of mammography is highest among women 50 years and older, since they tend to have reduced breast density due to increased fatty tissue within the breast. Conversely, sensitivity is lowest among women younger than 50 years due to their increased breast density, though rapid tumor growth is more likely to occur in this younger population.[42] Based on this information, the U.S. Preventive Services Task Force issued new guidelines in 2009 recommending against routine mammography screening in women between 40 and 49 years; it called for biennial mammography screening for women between the ages of 50 and 74 years.[5] In contrast, the updated American Cancer Society screening guidelines recommend that women 40 to 44 years be given the choice of undergoing annual mammography; those 45 to 54 years have annual mammography; and those 55 years and older have biennial or annual mammography as long as their overall health is good and they have a life expectancy of 10 or more years.[43]

Table 13-8 **Breast Screening Recommendations for Women Not at High Risk of Breast Cancer from Selected Organizations**

Age	USPSTF (2016)	ACOG (2017)	ACS (2015)	NCCN (2016)
Clinical Breast Examination				
25–39 years	Insufficient evidence to recommend for or against	May offer every 1–3 years	No recommendation	Recommend every 1–3 years
≥ 40 years	Insufficient evidence to recommend for or against	Recommend annually	No recommendation	Recommend annually
Mammogram Initiation Age and Frequency				
40–44 years	Screening at age 40 years is made on individual basis	Offer annual or biennial starting at 40 years	Offer annual	Recommend annual at age ≥ 40 years
45–49 years	Screening at age 40 years is made on individual basis	Initiate annual or biennial after counseling if woman desires screening	Offer annual	Recommend annual at age ≥ 40 years
≥ 50 years	Every 2 years until age 75 years.	Recommend annual or biennial if not already initiated	Recommend biennial with option to continue annual for women ≥ 55 years	Recommend annual at age ≥ 40 years
Mammogram Discontinuation				
	Insufficient evidence to recommend for or against at 75 years. Decision to be based on shared decision making.	Insufficient evidence to recommend for or against at 75 years. Decision to be based on shared decision making.	When life-expectancy is < 10 years	When severe co-morbidities limit life expectancy to ≤ 10 years

Based on U.S. Preventive Services Task Force. Screening for breast cancer: U.S. Preventive Services Task Force Recommendation statement. *Ann Intern Med.* 2016;164(4):279-296[5]; Oeffinger KC, Fontham ET, Etzioni R, et al. Breast cancer screening for women at average risk: 2015 guideline update from the American Cancer Society. *JAMA.* 2015;314(15):1599-1614[43]; American College of Obstetricians and Gynecologists. Practice Bulletin No. 179: breast cancer risk assessment and screening in average-risk women. *Obstet Gynecol.* 2017;130(1):241-243[44]; Gradishar WJ, Anderson BO, Balassanian R, et al. NCCN guidelines insights: breast cancer, version 1.2017. *J Natl Compr Canc Netw.* 2017;15(4):433-451.[46]

In 2017, the American College of Obstetricians and Gynecologists (ACOG) issued a position paper regarding screening for women at average risk.[44] Similar to the American Cancer Society, ACOG now recommends offering a woman in her 40s the choice of a screening mammogram, with annual or biennial examinations to follow at least by age 50.

The Canadian Task Force for Preventive Care guidelines for screening of women at average risk were last issued in 2011, though newer guidelines may be available in the near future.[45] In 2011, the Canadian group stated that the evidence for making recommendations was weak, and suggested no screening for a woman in her 40s, with mammograms occurring every 2 to 3 years for women age 50 to 74 years.

The National Comprehensive Cancer Network (NCCN) is a consortium of almost 30 cancer centers in the United States. Most of these centers are designated by the National Cancer

Institute (one of the National Institutes of Health) as comprehensive cancer centers. This group also has issued separate screening guidelines that have small variations from those proposed by the other groups.[46]

Discontinuation of Screening. Similar to the controversy about when to initiate screening and at what frequency, there is debate about the appropriate age at which to discontinue screening mammograms. The U.S. Preventive Services Task Force has stated there is insufficient evidence when to discontinue such screening, although several groups recommend discontinuation if life expectancy is 10 years or less.

Table 13-8 provides a brief summary of the current recommendations of various groups for screening of women who are not at high risk for breast cancer. The variations in these guidelines present a challenge for a midwife in practice. Ideally, healthcare providers should choose one guideline instead of alternating among them.[28,43,44,46]

Digital Breast Tomosynthesis

A new mammographic technique, known as digital breast tomosynthesis, provides a three-dimensional picture of the breast using X rays. This more detailed mammographic technique is approved by the U.S. Food and Drug Administration, but is not yet considered the standard of care for breast cancer screening. Two prospective population-based studies showed that digital breast tomosynthesis significantly increased breast cancer detection rates among women screened with both the standard digital mammography and digital breast tomosynthesis performed at the same screening episode.[47,48]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is the most sensitive test for breast cancer. Nevertheless, due to its high expense, it is recommended only for screening of women who are at very high risk for breast cancer, such as those who are positive for the *BRCA* gene mutation. MRI is recommended for use in conjunction with mammography as indicated.[49]

Ultrasonography

Ultrasonography is employed to screen the breast tissue of younger women at increased risk for breast cancer, diagnostically to differentiate between solid and cystic breast masses, and to guide fine-needle biopsies. The performance of this test is not affected by breast density. The American College of Radiology Imaging Network's randomized trial showed that adding ultrasound to mammography screening in high-risk women with dense breasts improved the sensitivity of the screening, but also increased the rate of false-positive examinations.[50] Women who are at high risk for breast cancer most likely are more fearful of a delayed diagnosis of breast cancer than of a false-positive result.[2]

Screening for Women at High Risk for Breast Cancer

In contrast to the multiple guidelines found in **Table 13-8**, recommendations for screening women who are at high risk for breast cancer are lacking.[51] Although there is a general consensus that women with the *BRCA1* or *BRCA2* genes should have early screening, some sources recommend starting at age 30 years and others at age 40 years. No evidence exists that the X rays in mammograms increase cancer risk among these women. Because MRI tends to have a higher degree of specificity compared to mammograms, there appears to be a movement toward annual MRI for this population. The use of MRI as a screening modality is also suggested for women who have a lifetime risk of 20% or more for breast cancer.[52,53]

Since care of women at high risk of breast cancer varies regionally, it is wise for midwives to establish lines of collaboration with experts in the area so that screening can be accomplished in a standardized manner. In addition, such collaboration enables the midwife to provide appropriate anticipatory guidance for women with increased risk of developing such malignancies.

Diagnosis of Breast Cancer

The majority of screening modalities report normal findings. When abnormalities are found, however, diagnostic testing is the next step. In many situations, these tests are performed by healthcare professionals in the local area.

The definitive diagnosis of breast cancer is generally made through tissue sampling. This can be accomplished through fine-needle aspiration, mammography- or ultrasound-guided core-needle biopsy, or excisional breast biopsy. The tissue sample obtained through the selected modality is then sent for histologic examination. If cancer is present, the histology report will state whether the tumor is ductal or lobular in origin. When the diagnosis of cancer has been made, it is also necessary to assess the lungs, abdomen, brain, and bone for metastasis.

A commonly used diagnostic test is fine-needle aspiration, also called fine-needle aspiration biopsy or fine-needle aspiration cytology. With this test, a physician inserts a thin (23–25 gauge), hollow needle into the breast mass and uses it to withdraw cells. Placement of the needle is performed under ultrasonic guidance and as an outpatient procedure. The cells obtained via fine-needle aspiration are subsequently evaluated specifically for malignancies.

Once breast cancer has been diagnosed, the malignancy is staged using the TNM system, which describes characteristics of the tumor (T), involvement of regional lymph nodes (N), and presence or absence of distant metastasis (M). Each cancer type (e.g., breast, brain, colon) has its own classification system, so letters and numbers do not always mean the same thing for every type of cancer; thus, the specific lexicon for breast cancer is used in this situation.[53] The TNM system is used in conjunction with staging, which is helpful as a guide to determine appropriate therapy options.[53]

An essential component of staging is investigation of the axillary nodes. In women with Stage I or II breast cancer, sentinel lymph node biopsy is performed. This is accomplished by injection of radioisotope dye into the breast tissue surrounding the cancer site so as to locate

the axillary node to which the dye initially spreads. The tissue from this node is then examined intraoperatively for cancer cells. If the sentinel node is positive for breast cancer, additional axillary nodes will be removed for evaluation. If the staging indicates greater than Stage II cancer, an axillary node dissection of at least 10 nodes from the first two levels of lymph drainage in the breast is indicated.

In addition to staging, the receptor status of the tumor is assessed. This evaluation provides information for treatment options and serves as an indicator of breast cancer prognosis. For example, the presence of estrogen and progesterone receptors improves prognosis, whereas over-expression of the growth factor receptor coded by the oncogene *Her2/neu* confers a poorer prognosis.[54,55]

Paget Disease and Inflammatory Breast Cancer

Although most breast cancer is associated with breast masses, Paget disease of the breast, also termed Paget disease of the nipple, is a rare cancer that involves changes of the nipple and areola. Women may report burning or itching of the nipple as a reason for a visit to a healthcare provider. The skin may have the appearance of eczema. Paget cells are malignant cells that are pathognomonic for the cancer. Most women with this disorder will be found to have ductal carcinoma in situ or invasive breast cancer.[56] Several other diseases bear similar names, such as Paget disease of the bone, but are distinct diseases—they share only the name of the physician who first described them.

Inflammatory breast cancer affects only a small number of women with breast cancer and without discrete masses. This condition often presents with a clinical picture similar to mastitis. This aggressive carcinoma involves the lymphatic system, and care for women with this cancer is best managed by a specialist in the area.

Treatment of Breast Cancer

Breast cancer treatment usually involves surgery, which may be followed with radiation therapy, chemotherapy, hormonal therapy, or immunotherapy. Radiation therapy or systemic therapies can be administered prior to surgery (neoadjuvant) with the goal of shrinking the tumor’s size, or they may be administered after surgery (adjuvant) with the goal of preventing cancer recurrence.

Most women with Stage I and Stage II breast cancers can be managed with breast-conserving surgery (lumpectomy) and sentinel node dissection, which is generally followed by radiation therapy. Breast-conserving surgery is contraindicated for women who have more advanced disease, women who have received previous radiation therapy, women who are pregnant (radiation is contraindicated in pregnancy), and women who have two or more primary tumors in separate quadrants of the breast or diffuse malignant-appearing microcalcifications. A history of collagen vascular disease (e.g., scleroderma or lupus) is a relative contraindication for breast-conservation treatment, as reports indicate that women with these diseases do not tolerate radiation.

Mastectomy involves removal of the breast tissue and the nipple/areolar complex, with

conservation of the pectoralis muscle, as well as sentinel lymph node dissection. Many women who are diagnosed with breast cancer are concerned about developing cancer in the contralateral breast and, therefore, request contralateral prophylactic mastectomy. The actual risk of developing contralateral breast cancer in the general population is extremely low (annual risk is 0.1% to 0.75%), so current breast cancer treatment guidelines strongly discourage this practice. However, women who are carriers of the *BRCA1*/*BRCA2* gene mutations have a 40% estimated 10-year risk of contralateral breast cancer; thus, contralateral prophylactic mastectomy may be recommended for these women, although the benefit of this preventive treatment when compared to conventional annual screening in this population is currently unclear.[57]

Radiation therapy after breast-conserving surgery reduces the recurrence rate for breast cancer by 50% and the death rate for breast cancer by 16.7%.[58] Radiation is used in conjunction with mastectomy only for late-stage breast cancers. In women with breast cancer who have axillary lymph node involvement, irradiation of the regional lymph nodes increases both disease-free years and survival years. Women need information about both the short-term (skin rashes and redness) and long-term side effects of radiation therapy (damage to the heart, lungs, or blood vessels in the chest; development of lung cancer; osteoradionecrosis).

Adjuvant (systemic) therapy is used to treat all stages of breast cancer and includes chemotherapeutic agents, hormonal therapies that are estrogen antagonists (e.g., tamoxifen, aromatase inhibitors) for cancer that is estrogen receptor positive, and immunotherapy (e.g., trastuzumab [Herceptin], a monoclonal antibody) for cancer that is found to overexpress the Her2/neu protein. All of these therapies are associated with a number of side effects. When considering the use of chemotherapeutic agents, it is important that the woman understands the associated side effects as well as her treatment options (**Table 13-9**).[53,55] For example, approximately 4% of women who take trastuzumab will develop ventricular dysfunction and congestive heart failure.[2]

Table 13-9 **Management of Common Side Effects of Chemotherapy for Breast Cancer**[a]

Side Effect	Management
Fatigue	Methylphenidate (Ritalin)
	Erythropoietin
Anemia	Iron supplementation
	Blood transfusion
	Erythropoiesis-stimulating drug (Procrit, Epogen)[b]
Neutropenia	Avoid contact with individuals who are sick or who are at risk for infection (e.g., schoolchildren)
	Agents that stimulate the production of neutrophils (Neupogen, Neulasta)
Nausea and vomiting	Eat small, frequent meals
	Stay well hydrated
	Avoid nausea triggers (unpleasant smells)
	Rest after eating
	Relaxation techniques
	Antiemetic drugs (e.g., ondansetron [Zofran], metoclopramide [Reglan], dexamethasone

	[Decadron])
Mucositis	Cold liquids and ice chips
	2% viscous lidocaine
	50/50 attapulgite/diphenhydramine (Kaopectate/Benadryl)
	Systemic analgesics
Diarrhea	Loperamide (Imodium)
	Octreotide (Sandostatin)
Constipation	Psyllium (Metamucil)
	Senna (SenoKot)
	Docusate sodium (Colace)
	Bisacodyl (Dulcolax)

[a] Many nonpharmaceutical treatments for breast cancer are taken based on anecdotal reports and lack evidence of effectiveness.

[b] The U.S. Food and Drug Administration has issued a black-box warning noting that studies have shown these drugs increase the risk of thromboembolic disease and may promote tumor growth.

Modified with permission from Carlson N, King J. Overview of breast cancer treatment and reconstruction for primary care providers. *J Midwifery Womens Health.* 2012;57(6):558-568.[55] © 2012, with permission from Wiley.

Breast reconstruction is an option for all women who undergo surgery. The reconstruction can be performed immediately post mastectomy or at a later time. Reconstructive surgery does not influence recurrence of the breast cancer or overall survival.

Follow-up

During the first 2 years after breast cancer treatment is completed, follow-up appointments generally occur every 3 to 6 months and include physical examination and mammography. Routine laboratory evaluation for metastasis (e.g., liver function tests, bone scans) is not recommended unless specifically indicated clinically.[59,60] Ovarian dysfunction is common in women of reproductive age who are treated for breast cancer, and reflects their age, ovarian function at the time of treatment, and the specific chemotherapy agents used. One study observed that 83.1% of women between the ages of 18 and 34 years resumed menstruating, on average, 3.5 months following breast cancer treatment; therefore, a discussion regarding contraception is merited.[61]

Contraception Following Breast Cancer

Breast cancer is a hormonally sensitive tumor and therefore, hormonal contraception is contraindicated for women with current or past history of breast cancer. Copper-containing intrauterine devices, tubal ligation, and vasectomy are considered to be better contraceptive options for women with a history of breast cancer.[62]

The safety of estrogen-containing hormone therapy for menopausal symptoms in women with a history of breast cancer is not well established. Nonhormonal treatments, such as selective serotonin reuptake inhibitors or gabapentin (Neurontin), are effective alternative options for the treatment of women with vasomotor symptoms. Vaginal estrogens are effective for the

treatment of women with atrophic vaginitis, although few data have been published on the safety of these medications in women with a history of breast cancer.[63,64]

Breast Conditions During Pregnancy and Lactation

The same breast disorders that occur in nonpregnant women can also present during pregnancy.[65] Notably, the breast examination can be more difficult when examining a pregnant woman secondary to engorgement and proliferation of breast tissue. Thus, small breast masses are more difficult to detect. Fibroadenomas can grow during pregnancy, and occasionally they may infarct and become painful. In addition, a few types of benign lesions are unique in pregnancy and lactation. The most common of these are lactational adenomas, galactoceles, mastitis, and breast abscess. The diagnosis and management of mastitis and breast abscess are reviewed in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

Lactational adenomas usually occur during the third trimester or during lactation.[66] These breast masses are similar to fibroadenomas in that they are painless, soft mobile masses. A lactational adenoma may appear as a fibroadenoma on ultrasound. These masses are not associated with an increased risk for malignancy.

A galactocele is a distended mammary duct with milk retention (milk retention cyst). Galactoceles usually present after cessation of breastfeeding.[66] They are usually round, soft, painless masses that may be associated with nipple discharge. Risk factors for galactocele include poor latch and abrupt cessation of breastfeeding. They usually regress spontaneously and do not require aspiration.

Breast Cancer

Treatment options for breast cancer during pregnancy are the same as for nonpregnant women, except for radiation therapy, which is considered to be unsafe for the embryo/fetus throughout all stages of gestation. It is also recommended that chemotherapy be delayed until after the first trimester of pregnancy due to an increase in spontaneous miscarriages as well as a possible increase in the risk for major fetal malformations secondary to exposure to chemotherapeutic agents. Chemotherapy in the second and third trimesters, while not associated with major malformations, may cause fetal growth restriction. Termination of pregnancy does not improve survival rates and is generally not recommended.[59,65]

Breast Cancer in Transgender Individuals

Transgender individuals may choose to undergo treatment to alter their breasts as they go through a transition from male to female/trans woman (e.g., hormone therapy, breast augmentation) or from female to male/trans man (e.g., mastectomy).

Trans women most often choose to take estrogen hormone therapy to create female secondary sex characteristics. Breast development in trans women on hormone therapy is rarely as complete as it is in genetic females, so many trans women will consider breast augmentation to add to breast volume. It is important when using estrogen that the risks versus benefits tradeoff be carefully evaluated for each individual. The standard mammography guidelines are recommended for this population given the lack of research regarding breast cancer risk in trans women.[67,68]

Trans men often perceive that breasts are a constant reminder of their biologic sex and may choose to either use a breast binder or pursue a mastectomy. If a mastectomy has not been performed, continued mammography screening is indicated. The risk for breast cancer after a mastectomy for this indication is rare, although the American Cancer Society recommends that women who have had mastectomies undergo CBE annually to evaluate the chest wall, skin, and incision. These guidelines can be extrapolated to transgender individuals even though the recommendations do not specifically identify their applicability.[67,68]

Conclusion

The midwife may be the first healthcare provider a woman consults for breast-related concerns. Breast cancer is one of the most frequently diagnosed cancers in women throughout the world. Screening and early detection are essential components of primary care services provided by midwives. The midwife is also an important member of the multidisciplinary team caring for a woman with the diagnosis of breast cancer, and fulfills this role by providing accurate information and support as the woman is making decisions regarding breast cancer treatment, and management of symptoms.

CHAPTER

14

Reproductive Tract and Sexually Transmitted Infections

Introduction

A woman's overall well-being includes sexual and reproductive components. The healthy expression of sexuality and the ability to safely engage in sexual and reproductive behaviors is supported by national and international organizations such as the United Nations,[1] the World Health Organization (WHO),[2] and the *Healthy People* initiative in the United States.[3] Unfortunately, women across the globe continue to struggle to obtain services to improve their sexual and reproductive health. Midwives are ideal care providers for women's sexual health needs, which include screening, diagnosis, and treatment of infections in women and their partners. This chapter reviews midwifery care for women with reproductive tract and sexually transmitted infections (STI).

Sexually transmitted infections are diseases that are passed from one person to another through sexual contact and sometimes via genital contact. Some STIs, such as gonorrhea, are transmitted only via exchange of body fluids during sexual contact; this chapter primarily focuses on these diseases. However, it is possible to spread a wide variety of infections and parasites through sexual contact. Some conditions that are not traditional STIs but are easily transmitted during sexual contact are included in the final section of this chapter.

A broad range of terms have been used to describe conditions that are transmitted through sexual contact. Many of these terms, including *venereal disease*, may have connotations of judgment or shame related to their use with public health campaigns. To avoid these negative stereotypes, the term *sexually transmitted disease* became more commonly used, and is the current term of choice of the Centers for Disease Control and Prevention (CDC). However, the term *sexually transmitted infection* (STI) is more precise, as not all sexually transmitted pathogens have immediate disease manifestations. The term "sexually transmitted infections" will be used throughout this chapter for precision and clarity.

Incidence of Sexually Transmitted Infections

STIs impact health across the life span, having both wide-ranging and persistent effects. According to the WHO, more than 357 million cases of curable STIs occur annually.[2] The CDC reports that 20 million new STI infections occur each year in the United States, with an immediate cost of more than $16 billion.[4] While immediate costs are easy to calculate, the long-term costs of STIs may be much higher, as such infections are associated with cancer, pelvic inflammatory disease, infertility, ectopic pregnancy, and lifelong malformations and blindness in infants born to women who have an STI during pregnancy or at the time of birth.[2]

Sexually transmitted infections vary greatly in incidence by geographic area, even within the United States. In addition, many variants or strains of an infection may occur, and the prevalence of these strains differs. If a woman or her partner is new to the geographic area or has recently traveled to another location, it can be useful to check treatment guidelines developed in the geographic area where the infection may have originated. For example, the antibiotic resistance profile of *Neisseria gonorrhoeae* varies by geographic region.[5] National and international organizations monitor the prevalence of infections and their susceptibility to treatment and produce reports to guide clinical management. However, with increasing global

travel, women may be infected with strains or subtypes not typical for their current location.

The prevalence of STIs also varies by personal risk factors. Women have a disproportionate health burden from STIs. Compared to men, women are more likely to contract an STI from a single sexual encounter and are more likely to have long-term sequelae.[2] In addition, women are often disproportionately stigmatized for having an STI due to taboos surrounding female sexuality. Furthermore, accessing appropriate and affordable services related to STI care and prevention may be difficult for some women.

The CDC monitors reportable diseases, such as chlamydia, gonorrhea, and syphilis.[4] Current information about these conditions is maintained on the agency's website and is available through its state-by-state interactive atlas.[6] The CDC also periodically updates guidelines for diagnosis and treatment of STIs; these guidelines, which were most recently updated in 2015, are extensively used in the United States.[7] The CDC guidelines can be downloaded, and paper copies can also be ordered.[7] In addition, the CDC has free apps to assist clinicians in accessing guidelines quickly at the point of care (see the Resources section at the end of this chapter). The U.S. Preventive Services Task Force (USPSTF) also releases guidelines that address STI screening based on current evidence. In addition, the Agency for Healthcare Research and Quality (AHRQ) has a mobile electronic device application that displays the USPSTF-recommended STI screenings based on the individual's age and risk factors.

While the CDC provides clear guidance for STI treatment in the United States, these guidelines are not always appropriate in other countries because treatment availability, drug names, and antibiotic resistance vary by geographic location. The WHO and country-specific health organizations are the best source of current treatment information outside the United States.

History and Physical Examination for Vaginal Symptoms and Sexually Transmitted Infections

Women may come to see the midwife with concerns about vaginitis or STIs or present for a comprehensive physical examination. Begin any visit by asking the woman in an open and inviting tone the reason for her clinic visit. If a woman is concerned about her privacy, she may have not been completely forthcoming with previous staff. Give her a chance to talk without interruption, as listening patiently establishes rapport and provides important information.

Problem-Focused Visit

Ideally, the woman will have already participated in a more comprehensive visit that included a complete history and physical examination. In these cases, a targeted but thorough history of the symptoms is important. The chief concern should be used to generate a list of differential diagnoses. It is helpful to use a systematic method to assess the problem. Many clinicians use the OLDCARTS technique to assess the Onset, Location/radiation, Duration, Character, Aggravating factors, Relieving factors, Timing, and Severity of symptoms. After exploring the woman's chief concern for the visit, ask her about additional STI-related symptoms such as fever, sore throat, enlarged lymph nodes, sores in the mouth or genital area, dysuria, discharge, and dyspareunia.

Sexual History

Obtaining an in-depth sexual history helps determine the woman's risk for infections and the need for screening and prevention during both well-woman care and problem-based visits. The woman is an essential partner in her health care, and listening to her concerns and history is one of the first steps in establishing a trusting relationship. It is important to be respectful when obtaining a thorough sexual history. While striving to put the woman at ease, the clinician should not shy away from asking personal questions. It is crucial to know the extent and location of previous and current sexual contact. For example, a vaginal test for gonorrhea would be useless if the woman has engaged in only anal or oral intercourse.

A variety of approaches may be used when obtaining a thorough sexual history. Some midwives request the woman complete a paper form as a guide for discussion, while others talk through the entire history. It is important to provide privacy in which to complete the forms and a private space for discussion. A woman may be less forthcoming when others are with her, especially her parents or children. While she may want her family or friends nearby for support, it is ideal to speak with her alone at some point during her visit. When discussing sensitive topics, it helps if the midwife and the woman are seated on equal levels without anything blocking their vision. While taking note of key items discussed, the focus should be on the woman, rather than the chart or computer.

A guide for obtaining a sexual history can be found in the appendix *Collecting a Health History*, in the *Introduction to the Care of Women* chapter. It is important to ask questions (5 P's)[8,9] to obtain needed information without making assumptions about the woman's sexuality

or beliefs. Remain open and engaged no matter what she reveals, using open- and closed-ended questions as needed. Focus on building rapport and obtaining the needed information to guide your assessment. Teaching about safe practices can take place later in the visit.

Physical Examination for Vaginitis and Sexually Transmitted Infections

The physical examination for STIs includes evaluation of all systems that may be affected. These systems are included in a complete well-woman examination but are examined individually during a targeted physical examination. **Table 14-1** provides a list of important systems to include in a targeted examination if the woman or midwife has concerns about STIs. While looking closely for STIs, take a holistic approach to the examination and avoid ruling out non-STI-related diagnoses too soon. A comprehensive and gentle physical examination can reveal many non-infection-related abnormalities that may be causing symptoms. Although laboratory data can be very valuable in the diagnosis of an STI, the physical examination is important to help determine which laboratory tests are indicated. In addition, treatment may be initiated on the basis of physical findings without waiting for laboratory confirmation.

Table 14-1 Physical Examination for Sexually Transmitted Infections

Organ/System	Abnormal Findings Related to STIs
Mouth	Lesions, pharyngitis
Cervical lymph nodes/chains	Palpable lymph nodes, possibly painful
Abdominal palpation	Abdominal tenderness
Inguinal lymph nodes	Palpable lymph nodes, which may be fluctuant or draining
Inspection of the pubis	Parasites, lesions, excoriations
Vulva, vagina, and perineum	Lesions, warts, excoriations, edema, discharge
Paraurethral (Skene's) glands	Enlarged glands, discharge on palpation
Greater vestibular (Bartholin's) glands	Enlarged glands, discharge on palpation
Urethra	Inflammation, swelling, discharge
Rectal area and anus	Lesions, warts, excoriations, signs of trauma
Speculum examination	Lesions, discharge, color, and character of vaginal walls
Vaginal mucosa	Overall appearance, lesions, discharge
Cervix	Wet mount, gonorrhea and chlamydia tests, cultures/testing of lesions, HPV testing with Pap test
Obtain needed specimens	
Bimanual examination	Enlarged uterus could indicate pregnancy; tenderness is a symptom of PID
Uterus	
Cervix	Cervical motion tenderness is a sign of PID
Adnexa	Adnexal tenderness is a sign of PID (and ectopic pregnancy)
Urine testing as indicated (nitrites, leukocytes, NAAT for gonorrhea and chlamydia)	Urinary tract infection signs include nitrites, leukocyts Urine test for chlamydia and gonorrhea is appropriate for screening and testing
Blood work as indicated (HIV, VDRL/RPR, HSV, hepatitis B)	Blood testing can confirm or enhance physical examination findings

Abbreviations: HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; NAAT, nucleic acid amplification test; PID, pelvic inflammatory disease; RPR, rapid plasma reagin; STI, sexually transmitted infection; VDRL, Venereal Disease Research Laboratory test.

Vaginal Microbiome

The bacteria that are normally present in the vagina serve as the first line of defense against vaginal infection.[10] These bacteria can prevent infection via either competitive exclusion or direct killing. In addition, the vaginal bacteria produce agents such as lactic acid that creates a pH level, which is inhospitable for some pathologic organisms.

A healthy vaginal flora is usually dominated by *Lactobacillus* species, especially *L. crispatus*.[10,11] However, the mix of organisms that constitutes a healthy vaginal microbiome differs by race and ethnicity and many modifiable factors such as smoking, sexual behavior, intravaginal practices, and diet. In addition, the vaginal microbiome may be an important mediator explaining some of the link between socioeconomic factors and increased risk for STIs. Dysbiosis—the term used to describe an unhealthy vaginal microbiome—is a known risk factor both for acquisition of STIs and for adverse reproductive outcomes.[11,12]

A great deal remains to be learned about the vaginal microbiome and its relationship to health. The role of modifiable factors, metabolic interactions within the vaginal microbiome, and the effects of treatment of dysbiosis are largely unknown at this time. That said, health education about modifiable factors that dysregulate the vaginal microbiome should be included in all health counseling about vaginal infections and sexually transmitted infections. A review of preventive strategies can be beneficial for women of all ages; the points to be covered in such a review are summarized in **Table 14-2**.

Table 14-2 Health Education for Prevention of Vaginal Irritation and Vaginitis

General Health Measures That Support a Health Vaginal Microbiome
Avoid cigarette smoking.
Avoid foods that have high dietary fat content and glycemic load.
Cleaning the Vulva and Vagina
Clean only the outside of the vagina with gentle, unscented soap.
Do not douche, as it eliminates helpful bacteria and increases risk of infection.
Use unscented, dye-free soaps, especially on the hands, anal areas, and genital areas of the woman and her partner.
Use a clean, previously dry washcloth or towel each time the vulva is cleaned or dried.
Wipe or pat the vulva gently after urinating; excessive wiping can damage the skin.
Cleaning with warm water after urinating and defecating can help some women.
Keeping the Vulva Dry
Gently but thoroughly dry the vulva after bathing; a hair dryer is ideal for this purpose.
Sleep without underwear to increase air circulation.
Cotton underwear (with a cotton crotch) is the most breathable.
Avoid staying in a wet bathing suit.
Avoiding Irritating Substances
Use unscented and dye-free detergents for underwear of both partners.
Double-rinse underwear to eliminate soap.
Avoid pads and panty liners unless needed, and try a variety of pads to find the least irritating.

Clean and gently dry the vulva as soon as possible after incontinence, as urine and stool are caustic to skin.

Altering Sexual Practices

Only clean objects should touch or enter the vagina (e.g., fingers, penis, sex toys).

Sexual contact should be gentle and nonpainful.

Use a water-based lubricant to prevent chafing during sexual activities.

Try a variety of pH-balanced lubricants to determine which is least irritating.

Clean objects (including fingers, penis, and sex toys) with soap and water after contact with the anus before they touch the vagina.

Consider condoms or nonvaginal ejaculation with recurrent infections, as semen may affect the pH of the vagina, especially when intercourse is frequent.

Choosing Birth Control

Spermicides may irritate the vagina.

Oral contraceptives alter the vaginal flora in some women, increasing their risk of vaginitis.

Reconsider use of these birth control method(s) for recurrent, severe vaginitis.

Vaginitis

Vaginitis, which is inflammation of the vagina, refers to a disruption of the normal healthy microbial environment within the vagina. Vaginitis, which is a common problem for women from menarche through menopause, can have many causes and origins that are not fully understood. Vaginitis can be a symptom of an STI, a disruption in the normal vaginal flora, or simple transient irritation of the tissue. Recurrent vaginitis can have many causes and warrants a thorough sexual and lifestyle history that includes evaluation of the woman's overall health and well-being, including information about behaviors of the sexual partner. While partner transmission of noninfectious vaginitis is not common, female and uncircumcised male partners may act as a bacterial reservoir, reinoculating susceptible women. Common vaginitis conditions include bacterial vaginosis, vulvovaginal candidiasis, and atrophic vaginitis.

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most common cause of vaginal infections in childbearing women[6] (**Figure 14-1**). Formerly known as *Gardnerella vaginalis*, *Haemophilus vaginalis*, or *Corynebacterium vaginitis*, BV is a dysbiosis of vaginal bacteria.[12] In essence, this infection represents a non-inflammatory disturbance in the vaginal microflora—which is why it is called *vaginosis*, rather than *vaginitis*. During episodes of BV, the vaginal flora is shifted toward a preponderance of anaerobic bacteria; these bacteria form a biofilm that adheres to vaginal epithelial cells.[13] In addition, production of volatile amines increases, and vaginal pH increases to more than 4.5.[14,15] Collectively, these changes result in a depletion of *Lactobacillus*.

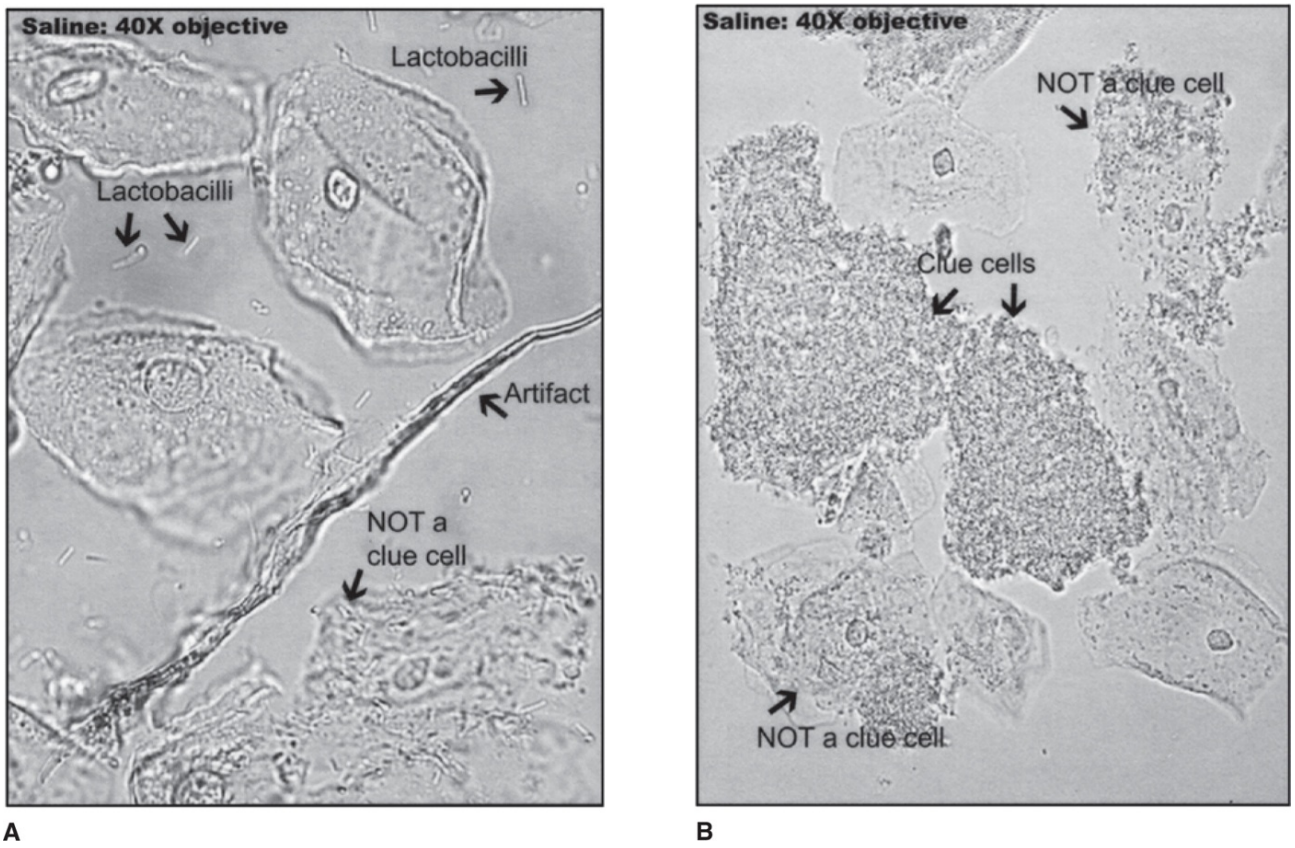

Figure 14-1 Microscopic diagnosis of bacterial vaginosis (BV). **A.** No BV; note the normal epithelial cells and presence of lactobacilli. **B.** BV; note the clue cells and lack of lactobacilli.
Reproduced with permission from Seattle STD/HIV Prevention Training Center and Cindy Fennell, MS, MT, ASCP.

Although the exact cause of bacterial vaginosis is not known, many factors are associated with its development, including smoking, menstruation, douching, sexual contact without a condom, low level of education, and engaging in oral or anal sex. This bacterial imbalance is associated with sexual contact, yet BV is not generally thought to be spread through sexual contact alone.[12-14] For example, the alkaline properties of semen may facilitate the vaginal flora's shift toward a predominance of anaerobic bacteria. Menopausal women have an increased risk for BV as a consequence of the decrease in healthy vaginal flora noted in

menopause. Women who have sex with women have increased prevalence of BV, and women of African descent have a higher prevalence of BV than women of other races, for unknown reasons.[12-14]

Bacterial vaginosis is associated with many adverse health outcomes, including preterm birth, postoperative infections, endometritis following pregnancy, and acquisition of other STIs.[15] However, this association is not fully understood, and treating BV does not prevent or mitigate the risk of associated adverse outcomes.[7,11,15]

Diagnosis of Bacterial Vaginosis

Symptoms of BV include vaginal irritation and itching, dyspareunia, gray or white discharge, and a "fishy" odor that is often most noticeable after vaginal penetration during sexual activity. Nevertheless, BV is asymptomatic in 75% to 85% of women.[15] On speculum examination, BV is usually evident as a thin white/gray homogenous discharge, irritated vaginal mucosa and introitus, and possibly cervicitis.

Gram stain with use of the Nugent scoring system is the gold standard for diagnosis of BV but is rarely available in outpatient settings. This test is time-consuming and requires laboratory equipment that is not always available in a clinic.[16-18] To make the diagnosis via clinical microscopy, a sample of the vaginal discharge is collected with a swab as described in the appendix *Collecting Urinary, Vaginal, Cervical, and Rectal Specimens for Testing and Interpretation of Saline and KOH Slides*, in the *Introduction to the Care of Women* chapter. The sample is first tested to determine the pH, and then a sample of the discharge is placed on two slides. Normal saline is added to one slide, which is covered with a slide cover and then set aside for microscopy. Finally, potassium hydroxide (KOH) is added to the other slide, which is used immediately for the "whiff test."

Studies have confirmed the sensitivity and specificity of individual components of Amsel's criteria for diagnosis of BV.[15-18] Clinically, BV is diagnosed when three of four of Amsel's criteria are present:

1. Presence of a thin homogenous discharge that adheres to vaginal walls
2. Presence of clue cells on the normal saline–prepared slide
3. pH of the vagina or vaginal discharge is 4.5 or higher
4. Positive "whiff test," which signals the release of an amine "fishy" odor when vaginal discharge contacts alkaline KOH

Alternatively, BV can be diagnosed with commercially available tests such as Affirm VP III, a DNA probe for *Gardnerella vaginalis*, or the OSOM BV Blue Test, which detects an enzyme produced by common BV-related organisms. Both of these tests are approved for use in making the diagnosis of BV.[19] While the sensitivity and specificity of these tests for diagnosing BV are better than that of Amsel's criteria alone, they are also more expensive.[19] Other commercial tests are available but have not been endorsed by the CDC due to their low sensitivity and specificity or lack of validation.[7]

Screening and Treatment of Bacterial Vaginosis

Routine screening for BV is not recommended, but all women who are symptomatic should be tested and offered treatment if the diagnosis is confirmed. **Table 14-3** outlines pharmacologic treatments for BV.[7,20] The choices for treatment include oral medications such as metronidazole (Flagyl), clindamycin (Cleocin), and tinidazole (Tindamax), as well as vaginal medications such as metronidazole gel or clindamycin cream or ovules. Selection of a specific agent should be part of the shared decision-making process, as the drugs have different side effects. For example, drinking alcohol during treatment with metronidazole and for 24 hours afterward can cause severe nausea and vomiting. Vaginal creams may be perceived as messy, and those containing clindamycin can weaken latex condoms and diaphragms. To ensure the treatment is compatible with her lifestyle, the plan of care must be developed in partnership with the affected woman.

Table 14-3 Treatment for Bacterial Vaginosis

Recommended Treatments for Nonpregnant Women Generic (Brand)	Alternative Treatments for Nonpregnant Women Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women Generic (Brand)
Metronidazole (Flagyl) 500 mg orally twice a day for 7 days	Tinidazole (Tindamax) 2 g orally for 2 days	Metronidazole (Flagyl) 500 mg orally twice a day for 7 days	Vaginal administration of metronidazole (Flagyl) is preferred for breastfeeding women.
Metronidazole gel (MetroGel) 0.75%, one applicator full per vagina at bedtime for 5 days	Tinidazole (Tindamax) 1g orally for 5 days	Metronidazole (Flagyl) 250 mg orally three times a day for 7 days	Metronidazole (Flagyl) taken orally by nursing women is excreted in breast milk and has active metabolites, increasing infants' exposure, but has not been demonstrated to be harmful. Timing the dose after nursing may decrease infant exposure, or women may discontinue breastfeeding for 12–24 hours after taking the medication.
Clindamycin (Cleocin) cream 2%, one applicator full per vagina at bedtime for 7 days	Clindamycin (Cleocin) 300 mg orally for 7 days	Clindamycin (Cleocin) 300 mg orally for 7 days	
	Clindamycin (Cleocin) ovules 100 mg intravaginally at bedtime for 3 days	Clindamycin (Cleocin) cream 2%, one applicator full per vagina at bedtime for 7 days	

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

Some studies have shown that probiotics, especially *Lactobacillus crispatus*, can be helpful

in establishing a normal vaginal flora and reducing BV recurrence.[12,21] However, the safety and effectiveness of these therapies have not been established.

Health education includes the recommendation to abstain from vaginal intercourse during treatment and wash all objects before they touch the vagina. More information related to maintaining healthy vulvar skin and the vaginal microbiome can be found in **Table 14-2**. Receptive oral and anal sex may increase the risk for BV related to microbial inoculation. Condoms may reduce the risk of BV by preventing contact with alkaline semen.

Until a normal vaginal flora is reestablished, relapses are common, especially after menses. Relapses occur in part because the anaerobic bacteria involved in BV form a biofilm that resists treatment.[12] After initial treatment, follow-up with another evaluation is recommended only if symptoms persist or reoccur. Chronic reinfection warrants further investigation and more intense treatments as outlined by the CDC.

Management of Bacterial Vaginosis During the Perinatal Period

Bacterial vaginosis is associated with an increased incidence of preterm birth.[15] However, treatment of BV during pregnancy with metronidazole (Flagyl) does not lower the incidence of preterm birth and, in fact, may increase the preterm birth rate via one of several mechanisms.[22] Therefore, as in nonpregnant women, routine screening for BV is not recommended, but diagnosis and treatment are recommended for women who are symptomatic.

Vulvovaginal Candidiasis

Candidiasis is an overgrowth of a *Candida* (yeast) species that affects the vagina, vulva, groin, and other moist areas of the body. The most common cause is *Candida albicans*, but other species may also cause this STI and are harder to treat. While candidiasis can be found in many locations on and in the body, this section focuses on infections in the female genital region. Seventy-five percent of women will have vulvovaginal candidiasis (VVC), commonly known as a yeast infection, at some point during their life.[7]

VVC is classified as uncomplicated or complicated. Uncomplicated VVC is a common condition that occurs sporadically throughout a woman's life and is associated with mild to moderate symptoms and manifestations. If infections occur more than four times per year, produce severe symptoms, or occur in women who are immunocompromised, VVC is classified as complicated and requires more intensive treatment.[7] Recurrent VVC is more likely to involve different *Candida* species, such as *C. glabrata*, that are not responsive to conventional antimycotic treatments.[7]

Several factors can make conditions favorable for *Candida* growth and increase a woman's risk of developing candidiasis, such as wearing nonbreathable clothes or being in very humid or warm living conditions. The hormonal changes that occur during pregnancy and while taking oral contraceptive pills also increase risk. In addition, diabetes is associated with increased incidence of candidiasis. Antibiotics administered to treat any infection may alter the vaginal flora, thereby facilitating proliferation of *Candida*. Immunosuppressed states, like those seen in persons with human immunodeficiency virus (HIV) and persons using corticosteroids, can also increase the risk of developing candidiasis in the vulvovaginal region and other moist areas of the body. Although species of *Candida* can be passed between sexual partners, candidiasis involves an overgrowth of normal flora and is not contagious.

Diagnosis of Vulvovaginal Candidiasis

Symptoms of candidiasis include vaginal itching, burning, irritation, dyspareunia, and increased vaginal discharge. The vulva may be erythematous, be slightly swollen, and have areas of redness with 1- to 2-mm "satellite" lesions extending from the affected area on external examination. The vagina is often red and slightly edematous. The vaginal discharge is usually thick, white, and curd-like, but can also be thin and watery, or adherent to the vaginal walls. Douching can complicate the physical examination by washing away discharge. Manifestations of severe candidiasis include widespread and severe erythema, skin fissures, edema, and excoriations.

A wet mount may reveal a lack of lactobacilli on a saline preparation or the presence of hyphae and pseudohyphae with a saline or KOH preparation (**Figure 14-2**). However, lack of hyphae does not rule out candidiasis, especially for women experiencing recurrent or severe symptoms, as the species of *Candida* implicated in recurrent and infection—*C. glabrata*—does not form hyphae. A culture can be performed in the absence of hyphae to check for non-*albicans* varieties of yeast. Treatment can begin without waiting for culture results.

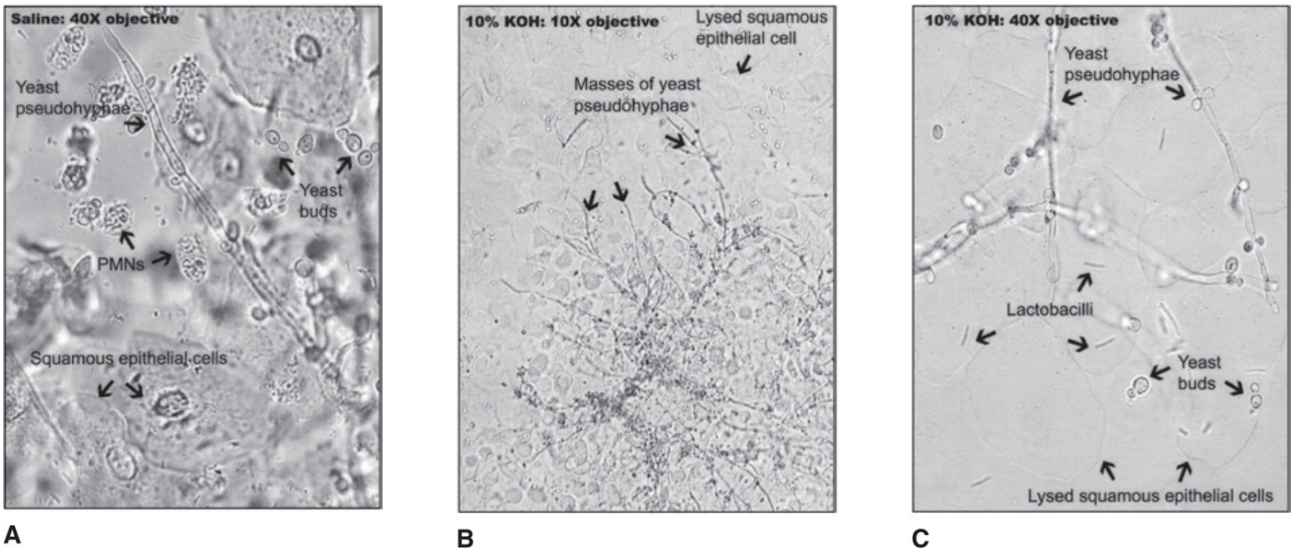

Figure 14-2 *Candida* pseudohyphae and budding spores under microscopic examination. **A.** Saline, 40×. **B.** KOH, 10×. **C.** KOH, 40×. Abbreviations: KOH, potassium hydroxide; PMNS, polymorphonuclear cells.

Screening and Treatment of Vulvovaginal Candidiasis

Routine screening for VVC is not recommended. Treatment options for VVC are listed in **Table 14-4**. Many of these treatments are available without a prescription, and women may use the medications prior to a clinical diagnosis of candidiasis. There is no standard recommendation about being seen by a healthcare provider prior to initiating treatment. Use of over-the-counter medications can decrease costs for women if they have VVC, but can also mean that women delay seeking treatment for harder-to-treat or more serious vaginal infections.

Table 14-4 **Recommended Treatment for Uncomplicated Vulvovaginal Candidiasis**

Agents	OTC or Rx	Brand Name	Dose	Duration
Intravaginal				
Butoconazole 2% cream (single dose bioadhesive patch)	Rx	Gynazole-1	5 g intravaginally once at night	Single dose
Clotrimazole 1% cream	OTC	Gyne-Lotrimin-7	5 g intravaginally once at night	7–14 days[a]
Clotrimazole 2% cream	OTC	Gyne-Lotrimin-3 or Clotrimazole-3	5 g intravaginally	3 days
Miconazole 2% cream	OTC	Monistat-7	5 g intravaginally once at night	7 days[a]
Miconazole 4% cream	OTC	Miconazole-3	5 g intravaginally	3 days
Miconazole 100 mg suppository	OTC	Monistat-7	1 suppository intravaginally once at night	7 days
Miconazole 200 mg suppository	OTC	Monistat-3	1 suppository intravaginally once at night	3 days
Miconazole 1200 mg suppository	OTC	Monistat-1	1 suppository	Single dose
Terconazole 0.4% cream (45 g)	Rx	Terazol-7	5 g intravaginally once at night	7 days
Terconazole 0.8% cream (30 g)	Rx	Terazol-3	5 g intravaginally once at night	3 days
Terconazole 80 mg suppository	Rx	Terazol-3	1 suppository intravaginally once at night	3 days
Oral				
Fluconazole	Rx	Diflucan	150 mg oral tablet once at night	Single

Abbreviations: OTC, over-the-counter; Rx, prescription.

[a] A 7-day course is recommended during pregnancy.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017.[7]

The class of medications used to treat VVC are antifungal agents that work by interfering with the formation of fungal cell membranes. Options include oral treatments, vaginal creams and tablets, and topical preparations. The costs and side effects of these therapies vary. All locations of infection (vaginal and/or vulva) should be treated. The creams require vaginal insertion, and they may weaken condoms. The oral medication fluconazole (Diflucan) does not require handling of the genitals but has systemic side effects including alterations in hepatic function and several drug–drug interactions.[7]

Complicated VVC in nonpregnant women, which includes skin fissures, should be treated with a longer treatment course of either 7 to 14 days of a topical “azole” or two doses of 150 mg fluconazole, 72 hours apart.[7] If the vagina is very irritated, topical creams may aggravate the discomfort experienced by some women. For the midwife treating a woman with candidiasis, it is important to involve the woman in choosing the route of administration and

medication.

Probiotics, especially oral *Lactobacillus*, may help to restore normal vaginal flora, but conclusive evidence is lacking in part due to variations in probiotic composition.[12] Douching is not a recommended treatment. Health education includes methods to decrease yeast growth by reducing vulvar moisture and eliminating irritants. Additional health information is found in **Table 14-5** later in this chapter. Some complementary medicine sources recommend lifestyle changes, including decreasing consumption of refined sugars and yeast products. While these strategies have minimal potential for harm, they have not been substantiated as beneficial in otherwise healthy women. There is no need for a test of cure if symptoms resolve; women should be rescreened only if they are symptomatic.

Recurrent Candidiasis

Recurrent candidiasis is defined as four or more occurrences of candidiasis within one year.[7] If a woman has recurrent candidiasis, assess for contributing lifestyle factors, including those related to care of the vulva, and perform a culture to test for non-*albicans Candida* strains. Testing for underlying diabetes or HIV infection may be indicated depending on the woman's history and risk factors. If the woman has severe, recurrent infections, she may consider changing her sexual practices or changing her birth control method to avoid spermicides and oral contraceptive pills.

A variety of treatment regimens for recurrent candidiasis are available. For recurrence of infection with *C. albicans* strains, longer duration of topical treatment combined with sequential oral treatment may be considered.[7] For non-*albicans* yeast, pharmaceutical-grade boric acid administered as a gelatin capsule that contains 600 mg; this capsule is inserted into the vagina once daily for 2 weeks.[7,23] Alternatively, 100,000 units of Nystatin (Mycolog) administered as a suppository per vagina for 14 days followed by a maintenance regime can be therapeutic.[7,23] Suppressive therapy can be considered once the infection is controlled and should be based on the type of yeast species.[7,23]

Atrophic Vaginitis

Atrophic vaginitis is a collection of vaginal symptoms related to low estrogen levels. Lower estrogen levels can cause vaginal changes, including decreased collagen and adipose tissue, and increased pH.[24] These changes make the vagina more friable and prone to irritation, and increase the risk of vaginal infections. Low estrogen levels can occur with natural menopause or cycle cessation during breastfeeding, chemotherapy, or treatment with gonadotropin-releasing hormone (GnRH) agonists such as leuprolide (Lupron). While not an infection, these changes place women at increased risk for other infections such as BV, candidiasis, and STIs.

Vaginal changes in menopause are normal and do not require intervention unless they adversely impact the woman's functioning or quality of life. Some women may be reluctant to disclose such problems, so questions about vaginal dryness, irritation, and dyspareunia are important history components in women who are menopausal or not having regular menses. Potential symptoms of atrophic vaginitis include vaginal irritation and dryness, frequent vaginal infections, dyspareunia, and lack of lubrication with sexual activity.

Diagnosis of atrophic vaginitis is made via physical examination. Factors that suggest diagnosis include thinning vulvar skin; decreasing prominence of the inner labia; small, nonelastic vaginal introitus; few vaginal rugae; pale pink vaginal walls; shortening of the vagina; and a lack of vaginal moisture. The woman's vaginal pH may be higher than 4.5.[24]

Over-the-counter, water-based vaginal moisturizers that contain polycarbophil and are mildly acidic, such as Replens, can decrease symptoms when used daily and are appropriate for most women. Use of water-based lubricant products such as Astroglide, K-Y Jelly, or K-Y Liquibeads during sexual activity can decrease discomfort. Regular sexual arousal, and sexual intercourse, can be helpful in improving vaginal blood flow to increase tissue health.[24] Other nonpharmacologic recommendations for mitigating symptoms of atrophic vaginitis can be found in **Table 14-2**.

Estrogen can also be used to alleviate symptoms of atrophic vaginitis. Topical estrogen administration via vaginal ring or cream is preferable to oral administration as a first-line pharmacologic treatment.[24] When used topically, estrogen does not need to be paired with progesterone in women with an intact uterus.[25] However, long-term data on the safety of topical estrogens are not available.[25] Some research supports the hypothesis that endometrial hyperplasia can occur with topical estrogen administration, especially with creams.[25]

If topical treatments are not sufficient to relieve severe symptoms, systemic estrogen or estrogen/progesterone can be used by menopausal or postmenopausal women, often in combination with topical estrogen.[24,25] However, oral estrogens have more side effects, including increased risk of ischemic stroke and venous thromboembolism. Breastfeeding women and women who are not cycling secondary to healthcare treatments should not be given systemic estrogens. If a woman has a history of cancer, she should consult a cancer specialist before using any estrogen-containing therapies.

Other Causes of Vaginitis

The skin of the vulva and vagina can become inflamed in response to many substances. For example, exposure to urine or stool, such as occurs with even mild incontinence, can cause chronic irritation and vaginitis. Perfumes and chemicals found in soaps, laundry detergents, and feminine hygiene products can also cause irritation. Personal lubricants can disrupt vaginal pH and normal flora, resulting in vaginitis. Spermicides may irritate the vagina as well. Douching washes away beneficial bacteria and irritates the vaginal mucosa, increasing the risk for vaginitis. A thorough exploration of all substances that contact the vulva and vagina is warranted for women who have unexplained or recurrent vaginitis. Women with incontinence should strive to keep the vulva dry and free of urine or stool, cleaning this area as needed with water and soft, nonabrasive wipes.

Anything left within the vagina can also cause vaginitis—including tampons, pessaries, or any other foreign body. Odor and irritation are often the presenting symptoms when a foreign object is in the vagina for longer than recommended use. A speculum examination can identify the cause of the odor in this situation. On speculum examination, a tampon may at first appear to be a fleshy mass, as it may blend in with surrounding tissue. Forgotten tampons have an extreme odor; thus a plastic bag or container with water should be prepared before their removal and the tampon immediately submerged as soon as it is removed. Tampons can be removed with ring forceps or digitally. Pessaries, when left in the vagina for long time periods, can become irritating, especially if the woman has atrophic vaginal changes. While an increase in vaginal discharge is normal with pessary use, it is important to assess for vaginal infections and skin erosions if the woman reports problems or discomfort.

Vaginal irritation can also occur during intercourse if the woman is not well lubricated or the contact is rough or damaging; this finding might be indicative of relationship problems and needs further exploration.

Sexually Transmitted Infections

Because sexual contact involves close bodily proximity, many microbes are shared between partners, most of which are nonpathogenic. The close contact of mucous membranes and the sharing of bodily fluids during such contact allow several pathogenic organisms the opportunity to find a new host. STIs may be caused by bacterial, viral, protozoal, or parasitic organisms, as shown in **Table 14-5**. Some clinicians, however, prefer to organize their list of differential diagnoses according to the woman's chief concern, as shown in **Table 14-6**. Many STIs are asymptomatic even while causing bodily damage. Anyone at risk for STIs should be screened according to CDC guidelines to prevent health sequelae and transmission to others. Pre-exposure prophylaxis for HIV or vaccination against hepatitis B may also be appropriate if women engage in at-risk behaviors.

Table 14-5 **Causes of Sexually Transmitted Infections**

Bacterial Disease (Organism)	Virus (Abbreviation)	Protozoal and Parasitic Disease (Organism)
Chlamydia (*Chlamydia trachomatis*)	Human papillomavirus (HPV)	Trichomoniasis (*Trichomonas vaginalis*)
Gonorrhea (*Neisseria gonorrhoeae*)	Herpes simplex virus (HSV-1 and HSV-2)	Pubic lice/crabs (*Phthirus pubis*)
Syphilis (*Treponema pallidum)*	Human immunodeficiency virus (HIV)	Scabies (*Sarcoptes scabiei*)
Chancroid (*Haemophilus ducreyi*)	Zika virus	
Lymphogranuloma venereum (*Chlamydia trachomatis* serovars L1, L2, and L3)		
Granuloma inguinale (*Klebsiella granulomatis*)		
Molluscum contagiosum		

Table 14-6 **Common Presenting Concerns for Sexually Transmitted Infections**

Increased Discharge (Organism)	Sores (Organism or Virus)	Lesions (Organism or Virus)
Chlamydia (*Chlamydia trachomatis*)	Herpes (herpes simplex virus [HSV-1 and HSV-2])	Genital warts (human papillomavirus)
Gonorrhea (*Neisseria gonorrhoeae*)	Syphilis (*Treponema pallidum)*	Condyloma acuminata (human papillomavirus)
Trichomoniasis (*Trichomonas vaginalis*)	Chancroid (*Haemophilus ducreyi*)	Condylomata lata (*Treponema pallidum*)
	Lymphogranuloma venereum (*Chlamydia trachomatis* serovars L1, L2, and L3)	
	Granuloma inguinale (*Klebsiella granulomatis*)	

General Management Considerations Specific to Sexually Transmitted Infections

When women have symptoms of an STI or possible exposure to an STI, management includes some unique approaches and special considerations.

Screening Strategies: Opt-in Versus Opt-out

Screening for any disorder can be offered in one of two ways. *"Opt-in"* (voluntary) refers to the individual being counseled about a test and then choosing or agreeing to have that screening test performed. *"Opt-out"* (universal) is a strategy in which the test is presented as part of standard care and unless the woman declines, the test is performed. Midwives using an "opt-in" approach ask women about STI tests individually and obtain consent to screen for each infection. This approach presents STI screening as routine, thereby normalizing testing, but it results in much lower rates of STI screening, as women are more likely to decline testing. By comparison, the opt-out approach, which has been studied with regard to HIV screening, greatly increases screening rates for HIV both during pregnancy and when people enter the hospital for care.[7]

The CDC advises clinicians to use an opt-out approach that presents women with a consent form that lists all of the common tests and allows them to opt out of any tests if they wish. Women should be informed of recommended tests and allowed to "opt out" of testing that is routinely recommended.[7] An opt-out approach to STI testing decreases barriers and presents these screening tests as tests that are routinely offered to all women.

Reportable Diseases

Most states in the United States require healthcare providers to notify the local health department when a person is diagnosed with certain communicable sexually transmitted diseases, as shown in **Table 14-7**.[26] Notifiable diseases are those for which obtaining information regarding individual cases is important for prevention and control of that disease. Reporting usually involves revealing the individual's name to the local health department and indicating whether the sexual partner was treated. The woman should be told that this report will take place. This information is used to notify and treat sexual partners and to monitor prevalence of STIs on local, state, and national levels.[9] U.S. law requires that the spouse (current or within the past 10 years) of a person who is positive for HIV be notified, and the health department can assist in this endeavor.[27] Midwives should be aware of the laws concerning partner notification in their state or legal jurisdiction.

Test of Cure, Test for Reinfection, and Pre-exposure or Postexposure Prophylaxis

Test of cure refers to the practice of reculturing a specimen from the site of initial infection to confirm that the infection is no longer present. A test of cure is recommended for some vaginal infections and STIs when the risk of therapy failure is well known and adverse outcomes are significant. A test of cure is performed shortly after the completion of therapy. In contrast, a *test for reinfection* is recommended when therapy is known to be highly effective but the partner may not be adequately treated. A test for reinfection is often performed a few months after completion of therapy.

Pre-exposure prophylaxis and *postexposure prophylaxis* may be recommended for women who are at risk for contracting HIV. These management strategies are reviewed in more detail in the section on HIV.

Expedited Partner Therapy

Treatment of the woman's sexual partner for STIs is within the scope of midwifery practice.[4] Partner treatment may involve examination and testing of the sexual partner or presumptive treatment without a clinic visit depending on the diagnosed STI. It is acceptable to treat male sexual partners for STIs without a physical examination—a practice known as *expedited partner therapy* (EPT).[28] EPT allows for rapid treatment of sexual partners, thereby reducing the risk of reinfection and decreasing healthcare costs. To prevent adverse outcomes from drug allergies, the clinician should provide information with the prescription about potential side effects and an allergy warning.

EPT has demonstrated positive outcomes for male sexual partners of adult women who have gonorrhea and/or chlamydia.[28] There is inadequate research to support EPT for trichomoniasis, however, and it is not well supported for use with partners of women younger than 19 years. Female partners of women with STIs should ideally be seen in the clinic to rule out pelvic inflammatory disease (PID). EPT should not be used to treat syphilis or long-term, chronic STIs such as herpes or HIV.[29]

EPT is a legally `sanctioned practice in 40 states, is potentially allowable in 8 states, and is expressly prohibited in 2 states.[28] Partner treatment is included in the American College of Nurse-Midwives' *Core Competencies for Basic Midwifery Practice*.[30] However, while a state may legally allow expedited partner treatment, some state licensure boards, such as boards of nursing, prohibit writing prescriptions for individuals who have not been evaluated

or who do not have a chart within the clinic of the prescribing provider. The CDC maintains an interactive database of state statutes concerning EPT that can provide guidance on pertinent state regulations.[31]

Indications for Sexually Transmitted Infection Screening

If a woman is concerned that she has been exposed to a STI, she should be offered tests for all STIs that are common in the geographical area, including those deemed most likely to occur based on her own or her partners' sexual behaviors.[7] Local and regional prevalence rates are used to determine which infections are prevalent in the region or in the woman's or her partner's area of origin.[6] The CDC provides a list of groups at increased risk for specific STIs.[7] The STI tests that are recommended by the CDC for women who are asymptomatic (pregnant or nonpregnant) are reviewed in **Table 14-8**.[7]

Table 14-8 CDC Screening Test Recommendations for STIs Among Asymptomatic Nonpregnant Women and Pregnant Women[a]

Infection	Nonpregnant Women	Pregnant Women
Chlamydia	Sexually active women younger than 25 years Sexually active women 25 years and older if at increased risk Rescreen for reinfection approximately 3 months after original treatment	All pregnant women younger than 25 years Pregnant women 25 years and older if at increased risk Rescreen for reinfection approximately 3 months after original treatment Test of cure 3–4 weeks after treatment Rescreen for reinfection during third trimester if younger than 25 or at risk
Gonorrhea	Sexually active women younger than 25 years Sexually active women 25 years and older if at increased risk Rescreen for reinfection approximately 3 months after original treatment	All pregnant women younger than 25 years Pregnant women 25 years and older if at increased risk Rescreen for reinfection approximately 3 months after original treatment
Hepatitis B	Women at increased risk	Test for HBsAG at first prenatal visit regardless of prior testing Rescreen for reinfection during intrapartum if at high risk
Hepatitis C	Women born between 1945 and 1965 Women at increased risk	Women born between 1945 and 1965 Women at increased risk
HIV	All women age 13–64 years with opt-out option[a] All women seeking STI evaluation	All pregnant women at the first prenatal visit with opt-out option Rescreen for reinfection during third trimester and during intrapartum if at high risk
HSV	Consider type-specific HSV serologic testing for women in high-prevalence settings (e.g., STI clinics) and those at risk (e.g., multiple sex partners)[a]	Although evidence does not support routine HSV-2 serologic screening tests for low-risk asymptomatic women, a type-specific test may be of value for women at risk of acquiring genital herpes during pregnancy[a]
Syphilis	Women at increased risk	All pregnant women at the first prenatal visit Rescreen for reinfection during third trimester and during intrapartum if at high risk
Trichomonas	Consider for women in high-prevalence settings (e.g., correctional facilities) and	Consider for women in high-prevalence settings (e.g., correctional facilities) and women at high risk (e.g., multiple

	women at high risk (e.g., multiple sex partners, drug use)[a]	sex partners, drug use)[a]

Abbreviations: CDC, Centers for Disease Control and Prevention; HBsAG, hepatitis B surface antigen; HIV, human immunodeficiency virus; HSV, herpes simplex virus; STI, sexually transmitted infection.

[a] Consideration based on evidence but not a CDC recommendation.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017.[7]

Recommended screening tests for STIs, for women of all ages, are discussed in greater detail in the *Health Promotion and Health Maintenance* and the *Prenatal Care* chapters. Women who are unable to conceive due to known infertility, menopause, or sterilization may neglect STI precautions. *Any* woman at *any* age who has a new or nonmonogamous sexual partner is at risk for STIs and should be offered testing. It is important to guard against age bias in the decision to offer STI tests; rates of STIs among people older than 50 years have been increasing.[32]

Any woman with symptoms of an STI, including urethritis, abnormal vaginal discharge, dysuria, cervicitis, or cervical motion tenderness, should be evaluated with a thorough history, targeted physical examination, and indicated laboratory tests. If a woman has one STI, she is at risk for having another, and should be offered tests for HIV and all common STIs.[7]

Half of all STIs occur in persons younger than 25 years.[6] The CDC recommends all sexually active women younger than 25 years be offered screening tests for chlamydia and gonorrhea annually.[7] In addition, they should be offered HIV screening (although the screening interval for HIV testing has not been determined) and other diagnostic tests if they are symptomatic. Pap testing with human papillomavirus (HPV) testing should begin at age 21 years, regardless of the number of sexual partners or age when the woman first became sexually active.

Adolescents can receive tests for STIs without parental notification or consent in all 50 states and the District of Columbia.[7] However, if a woman uses health insurance for payment, the services provided will be included on the insurance explanation of benefits, which could breach confidentiality.[7] Young women, especially those using parental insurance, should be informed about insurance reports. If the young woman wants to use parental insurance, it may be helpful to forewarn her parents that she was screened for STIs as a component of a recent healthcare visit. If this is not acceptable, it may be best to refer the woman to local resources for free or low-cost STI testing.

Women Who Have Sex with Women

Sex and sexual contact with female partners can pose a risk for STI transmission related to contact with skin, genitals, and oral and vaginal mucosa. While the prevalence of infections is different in women who have sex only with women, the guidelines for STI and cervical cancer testing do not change with the sex/gender of the partner.[7]

Sexually Transmitted Infections During Pregnancy

Sexually transmitted infections can adversely affect the embryo or fetus, causing a wide range of complications, including lifelong morbidity and intrauterine death. Early screening and treatment for STIs can prevent maternal and fetal/neonatal complications. For this reason, comprehensive STI testing should be performed during the first visit for pregnancy or as soon as possible. States often mandate the provision of these services within a set time frame. As a consequence, STI tests should not be delayed to coincide with other testing, such as routine second-trimester bloodwork. Women who have multiple sexual partners or women who are diagnosed with an STI during pregnancy should be rescreened in the third trimester or in labor if indicated. Women are rescreened during each pregnancy, regardless of interconceptional spacing.[7]

All pregnant women are offered testing for chlamydia and HIV using an opt-out approach in the first trimester, and women at high risk should be offered repeat screening tests in the third trimester. High-risk groups for chlamydia include women who have tested positive for chlamydia during the current pregnancy, who are younger than 25 years, or who have new, multiple, or nonmonogamous sexual partners. High-risk status for HIV is conferred by the following factors: living in a high-prevalence area, drug use, diagnosis of an STI during pregnancy, and new, multiple, nonmonogamous, or HIV-positive sexual partner(s). Even if screened earlier during pregnancy, women at risk for STIs should be rescreened in the third trimester or at the time of admission in labor. Some states mandate third-trimester testing for STIs unless the woman specifically declines such tests.[7]

Pregnant women who are considered to be at risk for gonorrhea and hepatitis C should be routinely screened for these STIs. At-risk groups for gonorrhea include individuals who have the following characteristics: living in an area with a high prevalence of gonorrhea, such as the southern United States; age younger than 25 years; a history of STIs; new or multiple sex partners; commercial sex work; drug use; and irregular condom use, which is common among pregnant women who may not consider the use of condoms for protection against STIs. Women who are at continued risk and those who acquire a risk factor over the course of pregnancy should be rescreened in the third trimester. The CDC recommends a one-time screening for hepatitis C for all adults born between 1945 and 1965. High-risk categories for hepatitis C include current or previous use of injected or intranasal drugs, obtaining an unregulated tattoo, and a history of blood transfusion or organ transplantation prior to 1992.

Regardless of their risk status, asymptomatic women do not need to be routinely screened for trichomoniasis or bacterial vaginosis during pregnancy. The degree to which identification and treatment of women with these conditions decreases adverse health outcomes and reduces the risk of preterm birth has been controversial. However, women should be tested if they have symptoms; if positive, they should be offered treatment following informed decision making based on health education about potential risks of preterm birth.[7]

Women Who Are Incarcerated

Women entering correctional facilities are a particularly vulnerable population, as the rates of STIs in this population are high.[33] Women who are incarcerated are more likely than those who are not to have been abused or exchanged sexual contact for food, housing, or money.[33] The

CDC recommends that on intake to a correctional facility and following consent, all females younger than 35 years be screened for gonorrhea, chlamydia, and HIV.[7] Syphilis screening in this population is based on local prevalence.[7]

Communicating Information About Sexually Transmitted Infections

Telling a woman that she has an STI is often difficult for both novice and experienced practitioners. The CDC advises clinicians to discuss positive HIV testing in person.[7] However, for STIs other than HIV, discussion of the diagnosis and planning for treatment may occur via the phone if an in-person visit is not feasible. Phone consultations are acceptable, but not ideal, as it is more difficult for the midwife to gauge how the woman is responding to the diagnosis. However, phone visits can facilitate prompt treatment and decrease the chance that the woman is unable to receive treatment. Prior to phoning a woman with STI results, make sure she consented to be contacted by phone. Once she answers, ask if she is in an acceptable location for the discussion before beginning the conversation.

Maintaining a normal tone of voice without judgment is helpful in being present for the woman. It may take time for the woman to adjust to the news that she has an STI. Openly discuss the fact that the infection is sexually transmitted and address whether it is possible for the infection to be transmitted in other ways, such as through common contact. While nonsexual transmission is possible with some infections, such as scabies, it is very unlikely for others, such as gonorrhea. Some infections produce symptoms soon after initial infection, whereas others, such as HPV, may not manifest for months or years. Avoid assumptions about the origin of the STI, and use open- and closed-ended questions to further explore the woman's feelings and needs. Always assess for the possibility of intimate-partner violence if the diagnosis is shared with a sexual partner. While health education to avoid future infections is needed, it can be difficult for a woman to concentrate on such health-promoting messages immediately after receiving an STI diagnosis. Written materials that the woman can take home will allow her to review the information when she is more receptive to it. A well-placed follow-up visit in person or by phone may be a better time for additional health education if the woman seems overwhelmed at the time of diagnosis.

Relationship Stressors and Violence

STIs can be associated with intimate-partner relationship difficulties. Although many STIs are acquired from a new partner who was previously infected, a new STI diagnosis may reveal infidelity of a long-term sexual partner or may be an indicator that the woman has been forced to have sex. Screening for human trafficking is warranted if the woman has more than one STI, an advanced case of the infection, or other risk factors for nonconsensual sex.[34] A diagnosis of an STI can spark or enhance relationship tension that may lead to negative emotions, cessation of the relationship, or even violence.[35] Even so, partner notification and treatment have not been shown to greatly increase the rate of violence.[35]

Psychosocial Needs

Women with STIs are more likely to be from vulnerable social groups. Being young, being poor, and using drugs are all risks for STI acquisition.[6] Sometimes sexual activity is one of

many risk-taking behaviors. In other cases, women did not have a choice about engaging in sexual contact. Women who are abused or forced into sexual encounters may not be able to advocate for condom use. Negotiating for safer sexual practices requires self-confidence and power within the relationship. Obtaining condoms requires money or access to services, which may be difficult to obtain for women of low socioeconomic status and those who do not have a support network. Women who trade sex for food, housing, drugs, or money or who are victims of trafficking are more likely to acquire STIs, as they often have multiple sexual partners who have little concern for the woman's health.[5] Women often enter care for one reason but have other needs besides the chief concern and can benefit from a holistic approach that provides them with needed information or referrals beyond their presenting diagnosis.

Contraception

Women who are sexually active with men are at risk for pregnancy. The time at which a woman is diagnosed with an STI presents an excellent opportunity to discuss her reproductive life plan. A critical first step in this discussion is to determine the woman's intentions regarding pregnancy. Straightforward questioning about whether she is planning a pregnancy in the near future can provide the midwife with answers that guide the discussion. For women who are planning a pregnancy, the midwife can use this opportunity to discuss the importance of pregnancy prevention until STI treatment is complete and returning for a test of cure if one is indicated.

When a woman is not planning a pregnancy in the near future, it is essential to review her contraceptive options and allow her to choose a method that provides prevention of unintended pregnancy as well as protection from STIs. Whereas both male and female condoms are part of safer sex practices, other birth control methods offer little protection from STI acquisition. However, condoms have a fairly high failure rate for pregnancy prevention and may be an inadequate primary contraceptive method. A woman may need to use condoms in addition to other contraceptive methods to prevent STIs and may need to be reminded of the importance of safer sexual practices even when she is not concerned about pregnancy prevention. Some women need guidance on how to negotiate for safer sexual practices even if they are protected from pregnancy.

Evaluation of the Need for Immediate Intervention, Consultation, or Collaboration

The treatment of women with STIs often involves interprofessional collaboration. Local pharmacists, physicians, and health department staff may be involved in this process. If the woman has a disseminated or advanced STI, hospitalization and consultation with physicians, pharmacists, and infectious disease specialists may be appropriate. Treatment failures may necessitate consultation with regional health departments or the CDC. Pediatric care providers need to know about any STIs in the pregnant or laboring woman that may affect her newborn or infant. Judicious use of other members of the interprofessional healthcare team can improve the quality of the care received while protecting a woman's rights and dignity. While consultation

may involve disclosing the woman's name and diagnosis, this should be done in ways that respect her rights and maintain her confidentiality. Care provider communication can facilitate quick and effective treatment, thereby preventing morbidity and mortality.[36]

Suspected sexual abuse of minors must be reported to local authorities for further investigation. In addition, reporting of STIs to local health departments is a responsibility that does not violate confidentiality. While local health departments should not reveal the name of the "index patient," there is the chance that someone could guess which partner had an STI, and this recognition could have wide-ranging implications for the woman, including violence. Therefore, the CDC advises all health departments to ask women, without coercion, to provide information about previous sexual partners so they can be notified and treated.[8]

Development of a Comprehensive Plan of Care That Is Supported by a Valid Rationale

It is important to ensure that women are treated appropriately for STIs to prevent short- and long-term morbidity and to reduce transmission. Treatment options can be presented to the woman and a plan of care developed to meet her needs. Effectiveness, cost, and convenience are chief considerations in choosing a treatment. Dosing frequency, privacy, and ability to apply or wash off the medicine may also be important in the decision-making process.

Follow-up after STI diagnosis and treatment differs by infection. While it can be difficult for women to return to the clinic, appropriate and well-timed follow-up is important to decrease infection-related morbidity, prevent transmission, and detect drug-resistant strains early.[7]

Chlamydia

Chlamydia trachomatis is a small gram-negative bacterium that is an obligate intracellular organism. Chlamydia is the most common reportable STI, with more than 1.4 million new cases occurring each year in the United States.[6] The majority of these infections occur in individuals 25 years or younger, although any sexually active person is at risk.[6] Because the majority of cases of chlamydia are asymptomatic, the CDC recommends screening all women who have a new sexual partner and annual screening for women 25 years or younger.[7]

When left untreated, chlamydia can ascend into the upper reproductive tract and cause pelvic inflammatory disease. Ascending infections increase the risk of subsequent ectopic pregnancy and infertility. Urogenital transmission is the most common form of spread of this infection, but sexual transmission to the oropharynx and rectum is possible. Vertical transmission can occur during vaginal birth, causing conjunctivitis or pneumonia in affected neonates.

Although chlamydial infection in women is usually asymptomatic, increased vaginal discharge, dysuria, or Bartholin gland infection can be presenting symptoms. Some women are initially diagnosed when they present with salpingitis (infection in the fallopian tubes) or PID.

Screening and Diagnosis of Chlamydia

All women who are younger than 25 years, have new or multiple sex partners, a sex partner with concurrent partner or a sex partner with STI, history of inconsistent condom use if not in a mutually monogamous relationship, drug use, sex work, history of a previous STI, or living in a geographic area with a high prevalence of gonorrhea (i.e., the southeastern United States) should be screened for chlamydia annually.

Physical examination may reveal cervicitis, mucopurulent discharge, or cervical motion tenderness. Although an increased number of white blood cells may be detected on a wet prep, diagnosis of chlamydia is made based on laboratory tests. Nucleic acid amplification test (NAAT) is the most common diagnostic test for chlamydia; it can be performed on urine, cervical, vaginal, or liquid cytology specimens.[7] NAAT detects small amounts of gene sequences in bacterial DNA and replicates those sequences so that a large amount is present. Most samples sent to the laboratory for STI diagnosis are tested with NAAT technology. Such tests may also be used with rectal samples, depending on the manufacturer and laboratory. Urine testing is the least invasive option and has high sensitivity rates.[7] NAAT on liquid cytology (liquid Pap test) may have a lower sensitivity for detecting infection.

Treatment and Follow-up for Chlamydia

Pharmacologic treatments for chlamydia are listed in **Table 14-9**.[7] Single-dose treatment is preferable. Ensure treatment of all sexual partner(s) from the last 60 days.[7] The woman with chlamydia should abstain from intercourse until her partner(s) are treated and for 7 days after single-dose treatment or until she completes her multidose treatment.[7]

Table 14-9 Treatments for Chlamydia

Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Breastfeeding Considerations
Azithromycin (Zithromax, Z-Pak) 1 g orally once	Erythromycin base 500 mg orally four times a day for 7 days	Azithromycin (Zithromax, Z-Pak) 1 g orally once	Azithromycin is compatible with breastfeeding.
Doxycycline (Vibramycin) 100 mg orally twice a day for 7 days	Erythromycin ethylsuccinate (E-Mycin) 800 mg orally four times a day for 7 days	Alternative treatments for pregnant women: amoxicillin 500 mg orally three times a day for 7 days	There is theoretical potential that an infant's forming teeth will become stained if doxycycline is used by a breastfeeding woman. However, its levels in breast milk are low and short courses of doxycycline are acceptable. If doxycycline is needed, consider strategies to minimize its transfer to the milk.
	Levofloxacin (Levaquin) 500 mg orally for 7 days	Erythromycin base 500 mg orally four times a day for 7 days	
	Ofloxacin (Floxin) 300 mg orally twice a day for 7 days	Erythromycin base 250 mg orally four times a day for 14 days	
		Erythromycin ethylsuccinate (E-Mycin) 800 mg orally four times a day for 7 days	
		Erythromycin ethylsuccinate (E-Mycin) 400 mg orally four times a day for 14 days	

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

Women who have a positive test for chlamydia should be tested for all common STIs, as coinfections frequently occur.[7] Nonpregnant women should be retested 3 months after treatment or at the next possible outpatient visit.

Management of Chlamydia During the Perinatal Period

Women with a history of chlamydial infection are at increased risk for ectopic pregnancy. The

CDC recommends routine screening for chlamydia for all pregnant women as early as possible during pregnancy. Pregnant women at increased risk for STIs (e.g., those younger than 25 years, those with a new or nonmonogamous sexual partner during pregnancy) are rescreened in the third trimester.[7] Treatment occurs as soon as possible after diagnosis, using a treatment regimen compatible with pregnancy. Pregnant women should be retested no sooner than 3 weeks after treatment and then rescreened again 3 months later or in the third trimester, whichever comes first.[7]

Chlamydial ophthalmia can cause ocular scarring and blindness and/or life-threatening pneumonia.[7] Because routine neonatal ocular prophylaxis is only 80% effective against chlamydia, infants born to women who are infected with chlamydia should be closely observed for symptoms but not routinely treated.[7] Additional information about eye prophylaxis for newborns to prevent chlamydial and gonorrheal ophthalmia can be found in the *Neonatal Care* chapter.

Gonorrhea

Neisseria gonorrhoeae is a gram-negative intracellular diplococcus that exclusively affects humans. This bacterium primarily infects the mucocutaneous surfaces of the genitourinary tract, pharynx, conjunctiva, and rectum. Gonorrhea is the second most common reportable communicable disease in the United States. In recent years, there has been a surge in antibiotic resistance to this organism, and the organism has the potential to become resistant to all currently available antibiotics.[6] The CDC and WHO monitor infectious disease resistance patterns and release updates as needed. Clinicians are advised to use the most current guidelines for the geographic location of acquisition and treatment.

Transmission of gonorrhea occurs through oral, anal, and vaginal sex and via contact with secretions from the source individual's urogenital tract. Vertical infection is possible during vaginal birth. Individuals infected with gonorrhea can be asymptomatic or may experience a variety of symptoms. Women may have dysuria, abnormal vaginal discharge, or bleeding if infected vaginally. Oral infection can result in a sore throat. Anal infection can cause anal itching, soreness, bleeding, discharge, or painful bowel movements.[7] Disseminated gonorrhea is a rare, life-threatening condition characterized by symptoms of joint pain and a rash. Gonorrhea can increase the risk of HIV acquisition and is associated with PID, infertility, and ectopic pregnancy.[7] Women with PID that is caused by gonorrhea can have fever, vaginal discharge, and abdominal pain. (See the section on PID.)

Screening and Diagnosis of Gonorrhea

Women at risk for gonorrhea include all sexually active women younger than 25 years and women with new sexual partners, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has an STI. Women at risk should be screened for gonorrhea annually.

The physical examination may be unremarkable in persons with gonorrhea. Conversely, lymph nodes surrounding the affected area may be enlarged. Urethritis and inflammation and discharge from the periurethral (Skene's) and greater vestibular (Bartholin) glands may be present. Cervicitis is common. If the woman has mucopurulent discharge from her cervix and uterus, adnexal tenderness, or cervical motion tenderness, PID is a likely diagnosis.

Diagnosis of gonorrhea is based on laboratory tests. However, if this infection is considered a likely diagnosis based on clinical findings, treatment can begin prior to knowing the results of testing. NAAT can be performed on endocervical, vaginal, or urine samples and is acceptable for initial screening and diagnosis of gonorrhea. NAAT products on the market have differing collection methods and sample requirements, so it is important to be familiar with the manufacturer's guidelines for each product. Cultures require an endocervical sample. If rectal, oropharyngeal, or ophthalmic testing is needed, ensure that the laboratory has tests that are specific to *N. gonorrhoeae*, as common bacteria present in these areas may cause false-positive results.

Treatment and Follow-up for Gonorrhea

Table 14-10 lists the recommended treatment regimens for uncomplicated gonorrhea infection. Ideally, treatment is provided on site and observed.[7] Women with gonorrhea are also frequently coinfected with chlamydia, so all CDC-approved treatments for gonorrhea include dual therapy treatment for chlamydia; this strategy is intended both to reduce the incidence of PID and to combat increasing antibiotic resistance.[7] Thus women with gonorrhea should be treated with azithromycin (Zithromax) in addition to ceftriaxone (Rocephin), even if they have a test for chlamydia that is negative.

Table 14-10 Treatments for Uncomplicated Gonorrhea of the Cervix, Urethra, Rectum, or Pharynx in Adults

Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women Generic (Brand)
Ceftriaxone (Rocephin) 250 mg orally in one intramuscular dose AND Azithromycin (Zithromax, Z-Pak) 1 g orally once	Use alternative only if unable to give ceftriaxone (Rocephin): Cefixime (Suprax) 400 mg orally in a single dose PLUS Azithromycin (Zithromax, Z-Pak) 1 g orally in a single dose	Same as for nonpregnant women	Same as for nonpregnant women

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

Alternative regimens are recommended only if ceftriaxone (Rocephin) is not available or if the woman is severely allergic to penicillin or cephalosporins. In such a case, a physician consultation should be obtained because the choice of cephalosporin needs to be individualized. The CDC website provides further guidance for unusual or complicated cases, such as treatment failure or disseminated gonorrhea.

Individuals receiving treatment for gonorrhea should be screened for other STIs, including syphilis, chlamydia, and HIV. They should abstain from sexual contact for 7 days after treatment and until all sexual partners are screened and treated. Otherwise, healthy nonpregnant adults with uncomplicated urogenital or rectal gonorrhea do not need a test of cure if treated with the ceftriaxone (Rocephin)/azithromycin (Zithromax) regimen. If treatment with ceftriaxone (Rocephin) was not possible or if the woman had pharyngeal gonorrhea, she will need a test of cure 2 weeks after finishing treatment using either NAAT or culture for the repeat test.

The CDC recommends rescreening for gonorrhea 3 months after treatment to test for reinfection.[7] If a 3-month rescreening is not possible, the woman should be screened the next time she presents for health care.[7] Most positive tests after treatment reflect reinfection; if treatment failure is suspected, a culture should be obtained, an infectious disease specialist or the CDC should be contacted, and the individual and her partner(s) should be immediately

treated using current CDC guidelines for treatment failures.[7] Pharyngeal gonorrhea is more prone to resistance than gonorrhea in other locations due to plasmid sharing with local microflora.[37]

Management of Gonorrhea During the Perinatal Period

Pregnant women at risk for gonorrhea should be offered a diagnostic test. Women with a history of possible exposure to gonorrhea can be offered treatment before the test results are available. Pregnant women should receive a test of cure following treatment and should be tested for reinfection in 3 months or during the third trimester.[7] If the woman is allergic to recommended treatments, consultation with an infectious disease specialist is recommended.[7]

Gonorrhea can be transmitted during birth and cause ophthalmia, localized infections of mucosa, abscesses at the site of a placed fetal heart rate electrode, or disseminated infection. Because gonococcal ophthalmia can result in permanent blindness, the CDC advises ophthalmia neonatorum prophylaxis using erythromycin ophthalmic ointment for *all* newborns, regardless of maternal testing status or route of birth; this prophylaxis is reviewed in more detail in the *Neonatal Care* chapter.[7] Many state laws mandate such treatment, and a parent must sign a waiver to opt out of treatment. Infants born to women with untreated gonorrhea or suspected gonorrhea should also receive parenteral antibiotics presumptively to prevent more severe infections.[7] Pediatric care providers should be notified at the time of birth if there is a concern the newborn has been exposed to gonorrhea.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is the term used to refer to a spectrum of disorders that are characterized by inflammation in the upper female genital tract; these disorders include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. PID results from a variety of causative organisms that ascend from the vagina into the upper urogenital tract, where they induce an inflammatory response.[38] *N. gonorrhoeae* and *C. trachomatis* are common causative organisms of PID. Abnormal vaginal microflora, such as BV, may increase the risk that pathogens will ascend into the uterus and fallopian tubes, causing PID. The onset of PID symptoms often occurs after menses, as the transient change in vaginal microflora during menstruation facilitates pathogen ascension into the uterus.[12] A slight increase in the risk of PID is also noted in the first few weeks following insertion of an intrauterine device (IUD), as pathogenic bacteria may be deposited in the uterus during placement.[39] While many risk factors for PID have been identified, including young age, HIV infection, and multiple or new sexual partners, any sexually active woman is at risk of developing this disease.

PID has many adverse short- and long-term sequelae for women. The inflammation from even mild cases of PID can cause scarring and permanent damage to tubal cilia, thereby impairing fertility and greatly increasing the risk of ectopic pregnancy throughout the reproductive years. Women may also develop chronic pelvic pain from PID-related adhesions.[38] Perihepatitis and tubo-ovarian abscess are immediate, severe risks of untreated PID. Both of these conditions cause severe abdominal pain. These conditions warrant further testing and hospitalization.[7] Because PID has severe, long-term outcomes, the threshold for diagnosis and treatment is low.[7]

Diagnosis of Pelvic Inflammatory Disease

To make the diagnosis of PID, the woman must have pelvic or lower abdominal pain and at least one of the following: (1) cervical motion tenderness, (2) uterine tenderness, or (3) adnexal tenderness. Additional symptoms, such as fever and mucopurulent vaginal or cervical discharge, increase the specificity of the diagnosis. Invasive tests are rarely warranted, as definitive diagnosis is not necessary before treatment is recommended. However, ultrasound and laparoscopy can be useful to rule out other diagnoses, such as ectopic pregnancy or acute appendicitis.[38] **Table 14-11** provides the full diagnostic criteria for PID.[7] A physical examination is needed to rule out other causes of abdominal pain, including gastrointestinal problems, ovarian cysts, and appendicitis or other surgical emergencies.

Table 14-11	Diagnostic Criteria for Pelvic Inflammatory Disease
Minimum Criteria (pelvic or abdominal pain AND one or more of the following criteria needed for diagnosis)	
Cervical motion tenderness OR Uterine tenderness OR Adnexal tenderness	

Additional Criteria (increase specificity of diagnosis)
Fever > 38.3°C (101°F)
Mucopurulent cervical or vaginal discharge
Numerous white blood cells on saline wet prep
Elevated C-reactive protein
Elevated erythrocyte sedimentation rate
Documented infection with *C. trachomatis* or *N. gonorrhoeae*
Definitive Criteria (not needed to begin treatment, but beneficial to rule out other diagnoses)
Transvaginal ultrasound, magnetic resonance imaging, or Doppler studies showing thickened and fluid-filled tubes
Laparoscopic visualization of pelvic inflammatory disease-related abnormalities

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017.[7]

When a woman presents with symptoms of PID, NAAT should be performed for gonorrhea and chlamydia; HIV testing is also recommended. A wide range of additional tests may be performed depending on the woman's clinical situation and the likelihood of other diagnoses. A wet mount that shows many white blood cells is suggestive of PID. Clue cells, positive whiff test, and altered pH may be present. Blood tests may reveal an elevated white blood cell count and erythrocyte sedimentation rate. A urine or blood test for human chorionic gonadotropin (hCG) might be needed to rule out ectopic pregnancy.

Diagnosis of PID is based on clinical presentation alone. The CDC advises a low threshold for diagnosis, as PID may have minimal symptoms but still cause tubal damage.[7] Laboratory tests for gonorrhea and chlamydia should be performed, but treatment should not be delayed while awaiting their results.

Treatment of Pelvic Inflammatory Disease

Women with PID are treated with antibiotics that provide a broad spectrum of coverage for both aerobic and anaerobic organisms. A woman with PID should be presumptively treated for both gonorrhea and chlamydia because a negative endocervical culture for one of these organisms does not rule out their presence in the upper genital tract (**Table 14-12**). Metronidazole (Flagyl) should be strongly considered to treat possible anaerobic organisms that may cause PID.[7] Oral treatment is acceptable unless the woman has not responded to oral treatment or is acutely ill. If a woman has an IUD in place, she should be treated as usual and the IUD does not need to be removed. That said, if the woman does not improve between 48 and 72 hours, the IUD should be removed.[7,40]

Table 14-12 **Outpatient Treatments for Pelvic Inflammatory Disease[a]**

Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women
Ceftriaxone (Rocephin) 250 mg IM once AND Doxycycline (Vibramycin) 100 mg orally twice a day for 14 days WITH or WITHOUT (literature favors with) Metronidazole (Flagyl) 500 mg orally for 14 days (for parenteral or inpatient treatment, refer to CDC guidelines)	A third-generation cephalosporin—such as Cefixime (Suprax) 400 mg orally in a single dose PLUS Azithromycin (Zithromax, Z-Pak) 1 g once a week for 2 weeks OR doxycycline (Vibramycin) 100 mg orally twice a day for 14 days WITH or WITHOUT Metronidazole (Flagyl) 500 mg twice a day for 14 days	Pregnant women with suspected PID should be hospitalized for evaluation according to CDC guidelines.	Same as for nonbreastfeeding women. Doxycycline is generally considered to be safe with breastfeeding, but longer courses of the drug have the potential to stain infants' teeth. Consider methods to decrease infant ingestion or an alternative regimen. Metronidazole administered orally to the mother is excreted in breast milk and has active metabolites in the infant. While no harm has been shown in breastfeeding infants, the potential amount ingested by the infant should be considered.
Cefoxitin (Mefoxin) 2g IM once AND Probenecid (Benemid) 1g orally administered as a single dose AND Doxycycline (Vibramycin) 100 mg orally twice a day for 14 days WITH or WITHOUT Metronidazole (Flagyl) 500 mg orally for 14 days	If woman has a severe cephalosporin allergy: Azithromycin (Zithromax, Z-Pak) 2 g orally once WITH or WITHOUT Metronidazole (Flagyl) 500 mg twice daily for 14 days		Probenecid may increase the excretion of cimetidine into breast milk.

Abbreviations: CDC, Centers for Disease Control and Prevention; IM, intramuscular; PID, pelvic inflammatory disease.

[a] For inpatient treatments, see the CDC guidelines.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

The symptoms of PID should improve dramatically within 72 hours after initiation of treatment. If no improvement is evident within this time frame, the woman should be reevaluated, and hospitalized for intravenous antibiotics and supportive therapy. Hospitalization should also be considered if the woman is pregnant; if oral treatment is not possible; when the PID appears to be severe, such as in the presence of a high fever or nausea and vomiting; and when emergencies such as appendicitis, tubo-ovarian abscess, or conditions cannot be excluded.[7,38]

Sexual partners from the 60 days preceding the onset of the woman's symptoms of PID should be treated presumptively for gonorrhea and chlamydia.[7] Health education includes recommending abstinence from sexual intercourse until therapy is completed and sexual partners have been treated, use of condoms, and other practices to decrease STI transmission, including HIV pre-exposure prophylaxis (PrEP) if indicated. If tests were positive for gonorrhea or chlamydia, the woman should be retested at 3 months or the next time she seeks health care.

Management of Pelvic Inflammatory Disease During the Perinatal Period

Women with a history of PID are at increased risk for ectopic pregnancy, and can benefit from early prenatal care. Although PID is rare during pregnancy, probably because of the protective effects of the cervical mucus, pregnant women with PID are at high risk for preterm labor and maternal morbidity. Pregnant women should be hospitalized for evaluation and treatment.[7]

Syphilis

Caused by a spiral-shaped spirochete (*Treponema pallidum*), syphilis is known as the "Great Pretender" because it may be asymptomatic or present with a variety of symptoms mimicking other conditions. The incidence of syphilis has been increasing in recent years, with a 27% increase in reported cases in women who reside in the United States between 2014 and 2015 alone.[5] Globally, 18 million people are infected with syphilis.[41] Transmission occurs through oral, anal, or vaginal sexual contact. Condoms do not fully protect against syphilis if the condom material does not cover all lesions.

Approximately 50% of individuals exposed to *T. pallidum* will develop infection if not treated. The disease progresses through three primary phases: primary syphilis (chancre and regional lymphadenopathy), secondary syphilis (disseminated skin eruptions and generalized lymphadenopathy), and tertiary syphilis (cardiovascular syphilis, neurologic symptoms and gummas [granulomatous lesions in skin and bone]).[41] A latent form of syphilis can develop between the secondary and tertiary phases. The three phases can overlap somewhat, and neurologic manifestations of syphilis can occur at any time in the disease process. In addition, a newborn may present with congenital syphilis, as the *T. pallidum* organism readily crosses the placenta.

Primary syphilis is characterized by a chancre that appears at the site of inoculation approximately 21 days after exposure. The chancre is a nontender indurated ulcerous lesion. It is usually a single lesion, filled with spirochete-laden purulent discharge, and is highly infectious. The chancre begins as a papule that erodes into a well-demarcated area, with induration of the base and circumference. Because the chancre is usually painless and heals spontaneously in 2 to 8 weeks, it may not be noticed, especially if it is inside the vagina or rectum. The chancre is an open wound, so it increases the risk of the woman developing other infections to which she might be exposed, including HIV and herpes. In addition, secondary infections may occur within the chancre, resulting in purulent discharge.

Secondary syphilis marks the change from local to systemic infection. The manifestations of secondary syphilis usually appear 4 to 10 weeks after infection, and can reappear following periods of latency. The most characteristic symptom of this stage of syphilis is a rash that appears on the palms of the hands, soles of the feet, and trunk; this rash can be macular, papular, or psoriasiform. Other symptoms include patchy alopecia, condylomata lata, lesions of the mucous membranes, and symptoms of a systemic illness such as low-grade fever, sore throat, hoarseness, malaise, headache, anorexia, and generalized lymphadenopathy. Condylomata lata can also occur; these highly contagious, flat, moist, wart-like lesions usually appear in body folds such as the vulva and perianal area.[41]

After the symptoms of secondary syphilis resolve, some affected individuals convert to early or late latent syphilis before the symptoms of tertiary syphilis appear. Persons with latent syphilis have no clinical manifestations, but their infection can be detected with blood serology tests. Individuals with latent syphilis who have been infected within the past year are classified as having early latent syphilis.[7] The WHO uses infection within the past two years to define early latent infection.[41] Individuals infected for a year or more are classified as having late latent syphilis and will need a longer course of treatment.

Tertiary syphilis can appear anywhere from one to two years after infection to 30 or more years later. Today, this form of the disease is rare in the developed world. Associated with high morbidity and mortality, tertiary syphilis takes two forms: gumma and cardiovascular syphilis.[7,41] Gumma are soft-tissue granuloma tumors, which occur in tissues throughout the body. These masses cause extensive damage within the body and are difficult to distinguish from carcinomas. Cardiovascular syphilis may result in aortic valve disease, aortic aneurysm, and coronary artery disease.[41]

Neurosyphilis can occur during any stage of syphilis. For women in the United States, clinical symptoms of central nervous system disease in the presence of positive serologic evidence of syphilis warrant examination of the cerebrospinal fluid.[7] The disease may also present as acute syphilitic meningitis, syphilis of the spinal cord, vascular neurosyphilis, or syphilitic eye disease.[41] The rate of congenital syphilis is increasing, with this rate increasing 38% between 2012 and 2014, from 8.4 per 100,000 live births to 11.6 per 100,000 live births.[42] This recent increase demonstrates the need for increased attention to screening and prevention of syphilis.

Screening and Diagnosis of Syphilis

Syphilis screening relies on one of two tests that look for the nonspecific antibodies that develop during this disease. The most common non-treponemal tests, known as VDRL (Venereal Disease Research Laboratory) and RPR (rapid plasma reagent), have a high false-positive rate. Pregnancy, autoimmune disorders, and acute bacterial or viral infections, for example, can cause a false-positive result on these tests. For this reason, all persons who have a positive non-treponemal test are retested with a confirmatory treponemal test such as fluorescent treponemal antibody absorption test (FTA-ABS), passive particle agglutination (TP-PA) assay, enzyme immunoassays (EIAs), or chemiluminescent immunoassays (CLIAs). The treponemal tests detect antibodies that are specific for *T. pallidum*.[7]

Laboratory testing for syphilis requires several steps, and different protocols can be followed. If a woman presents with a chancre, positive results on dark-field microscopy of exudate from the chancre lesion provide definitive diagnosis; however, dark-field microscopy is not available in all settings.[7]

The usual first step if no chancre is present is to screen with a non-treponemal test (VDRL or RPR); such a test is sensitive but not specific. If those results are positive, they are confirmed with a specific treponemal test. If no chancre is present, the VDRL and RPR tests may not be positive for the first few weeks of infection (false negative), or positive results on the tests may be secondary to other conditions (false positive).[7]

Although the initial diagnosis is based on a positive treponemal test, this test remains positive for life after infection; as a consequence, it cannot be used to determine the presence of active infection or response to treatment. Instead, serial quantitative non-treponemal titers of immunoglobulin antibodies are used to determine the response to treatment and to detect reinfection.[7]

The protocol for diagnosis and treatment of syphilis is more complex if the woman has a

previous history of syphilis or if she is HIV positive; the CDC guidelines specify testing strategies for current syphilis in such individuals. Symptoms of neurosyphilis are also an indication for more intensive screening in consultation with a specialist.[7]

Treatment of Syphilis

Parenteral penicillin G is the best treatment for syphilis. Other forms of penicillin are not as effective because they do not adequately penetrate into sequestered sites such as the central nervous system. **Table 14-13** identifies the recommended doses and routes of treatment based on stage of infection. While alternative treatments are provided for nonpregnant individuals, their efficacy has not been studied in depth. If a person has a penicillin allergy, consider skin testing for verification, especially for late latent syphilis or syphilis of unknown duration.[7] Individuals with tertiary syphilis, neurosyphilis, or ocular syphilis should be referred to a specialist for more intensive diagnostic testing and treatment.

Table 14-13 **Outpatient Treatments for Syphilis**

Stage of Syphilis	Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatment for Breastfeeding Women
Primary, secondary, and early latent syphilis	Benzathine penicillin G (Bicillin LA) 2.4 million units IM in a single dose	Doxycycline (Vibramycin) 100 mg orally twice a day for 14 days OR Tetracycline (Sumycin) 500 mg four times a day for 14 days Other regimens may be available in consultation with an infectious disease specialist.	Benzathine penicillin G (Bicillin LA) 2.4 million units IM in a single dose If the woman is allergic to penicillin, desensitize per CDC guidelines. Jarisch–Herxheimer reaction may cause preterm labor or fetal distress in the first 24 hours of treatment; consider additional monitoring.	Benzathine penicillin is safe during breastfeeding. Doxycycline and tetracycline have the theoretical risk of staining forming teeth. Longer courses of therapy with these drugs are not recommended for breastfeeding mothers. If alternative therapies are not available, consider strategies to minimize drug transfer to the breast milk.
Late latent syphilis or syphilis of an unknown duration	Benzathine penicillin G (Bicillin LA) 7.2 million units IM once a week for three doses	Doxycycline (Vibramycin) 100 mg orally twice a day for 28 days OR Tetracycline (Sumycin) 500 mg four times a day for 28 days For other therapies, consult an infectious disease specialist.	Benzathine penicillin G (Bicillin LA) 7.2 million units IM once a week for three doses	

Abbreviation: CDC, Centers for Disease Control and Prevention; IM, intramuscular.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

Clinical assessment and a non-treponemal test (VDRL or RPR) should be performed 6 months and 1 year following treatment to test for treatment effectiveness. With adequate treatment, titers usually decline fourfold (e.g., 1:128 down to 1:32), but in 15% of treated individuals, the titer does not decline. An increase in titers by fourfold following treatment is indicative of treatment failure or reinfection.

All women who have a positive test for syphilis should be offered HIV screening. Also, all of the woman's sexual partners from within the past 90 days should be treated presumptively for syphilis. If the person has secondary or early latent syphilis, previous sexual partners in the previous year may need to be notified and tested per CDC guidelines[7]; local or state-level health departments may be able to assist in this process.

Management of Syphilis During the Perinatal Period

Syphilis readily crosses the placenta after 9 weeks' gestation. Transmission of the pathogen to the fetus usually occurs between the 16th and 28th weeks of pregnancy.[43] As many as 40% of women with untreated syphilis during pregnancy will miscarry. Up to 80% of infants born to women with primary syphilis will have congenital syphilis, including congenital malformation, but the risk of vertical transmission decreases with the length of time the woman has been infected.[44,45] Syphilis is also associated with preterm birth, low birth weight, and congenital malformations. Thus screening for syphilis is recommended for all women at their first prenatal visit and rescreening recommended at 28 weeks for women who have a high risk for developing syphilis.

The diagnostic algorithm for detecting syphilis infection during pregnancy recommended by the CDC is the "traditional" algorithm, which screens first with a non-treponemal test (VDRL or RPR) test, which is then followed by a confirmatory treponemal-specific test. Some settings prefer the "reverse algorithm," in which a treponemal-specific test is used as the first screening, with any reactive samples then being tested quantitatively with a non-treponemal test.[45] Both algorithms have strengths and weaknesses that are influenced by the local prevalence of the disease and the cost-effectiveness of the algorithm in high- versus low-volume laboratories.

Penicillin G is the only acceptable treatment for syphilis during pregnancy. If a woman is allergic to penicillin, she should be desensitized prior to treatment.[7] Desensitization is a procedure that works to alter a person's immune reaction so that the body does not react to the antigenic agent. It is accomplished by administering sub-threshold doses of the medication that cause immunoglobulin E (IgE) to bind to basophils and mast cells, thereby making them unresponsive to higher doses of the drug.[46] An oral protocol for penicillin desensitization is recommended by the CDC.[7] The procedure should be performed only in a setting where resuscitative equipment is readily available.

Jarisch–Herxheimer Reaction

The Jarisch–Herxheimer reaction refers to the appearance of fever, chills, tachycardia, hypotension, and intensification of skin rashes within the first 24 hours of treatment for syphilis. This reaction is a response to lipoproteins from the spirochete that induce a systemic inflammatory response.[47] It can cause preterm labor and abnormal fetal heart rate changes, so additional monitoring during the first 24 hours of treatment may be indicated.[7] If the woman is treated for syphilis less than 4 weeks before giving birth, the newborn will need additional testing and treatment as outlined by the CDC.[7] Women without documented syphilis testing should be screened for syphilis during the intrapartum period.[7]

Congenital malformations are common in infants born to women with untreated syphilis during pregnancy, and include deafness, hepatomegaly, and bone abnormalities. Even when pregnant women receive treatment for syphilis, it may come too late in gestation to prevent congenital abnormalities.[43] Notify the infant's care provider of syphilis exposure to facilitate appropriate neonatal care. Syphilis can cause intrauterine fetal demise, and maternal screening

for syphilis is recommended following stillbirth at any gestation.[43] Syphilis can also cause the placenta to be large and pale. Infants born to women with positive serologic tests need in-depth evaluation, including testing of the placenta, serologic tests of the newborn's blood (cord blood is not acceptable), and dark-field microscopy testing of suspicious body lesions.[7] Abnormal results warrant treatment and more invasive testing per CDC guidelines.[7]

Chancroid

Chancroid ulcers are nonindurated painful lesions caused by a gram-negative anaerobic bacillus, *Haemophilus ducreyi*. The infection is transmitted through sexual contact with mucous membranes. These lesions are usually found on the vulva, cervix, or perineum, and approximately 50% of affected women have associated unilateral adenitis that can develop into buboes—that is, abscesses of the local lymph nodes. The buboes can rupture, spreading infection and leading to permanent scarring. While the incidence of chancroid has declined around the world, outbreaks continue to occur, often associated with the sale or exchange of sex.[41]

Diagnosis of Chancroid

Diagnosis of chancroid is based on the findings of a physical examination. The presence of a painful ulcer on the genitals combined with tender inguinal lymphadenopathy suggests chancroid. Lymph nodes may be fluctuant and drain when pressed. Because many infections can cause genital lesions (**Table 14-14**), it is important to perform several tests directly on the genital lesion, including cultures for herpes simplex virus (HSV) and secondary infections, and dark-field microscopy for syphilis. If possible, obtain a culture for *H. ducreyi*; however, the culture medium is not widely available and has a low specificity. The woman should also be evaluated for chlamydia and gonorrhea. If it has been more than 7 days since the lesion appeared, also perform a non-treponemal test (VDRL, RPR) for syphilis. Negative serologic tests for syphilis and wound tests that are negative for HSV and syphilis are needed for confirmation of chancroid diagnosis.

Table 14-14 Differentiation of Genital Lesions by Symptoms

Typically Painless	Typically Painful
Genital warts/condyloma acuminata	Herpetic vesicles and open lesions
Syphilis chancre	Chancroid
Condylomata lata	Lymphogranuloma venereum
	Lymphadenopathy and lesions

Treatment of Chancroid

Table 14-15 outlines pharmacologic treatment for chancroid. Single-dose therapy is preferred for ease of use. There have been reports of *H. ducreyi* resistance to ciprofloxacin (Cipro) and erythromycin (E-Mycin) outside the United States. All of the woman's sexual partners within the last 10 days preceding onset of symptoms should be treated presumptively for this STI, and the woman should be tested for HIV and syphilis at the time of diagnosis.

Table 14-15 Treatments for Nonsyphilitic Genital Ulcer Diseases

Genital Ulcer Disease	Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women Generic (Brand)
Chancroid	Azithromycin (Zithromax, Z-Pak) 1 g orally once OR Ceftriaxone (Rocephin) 250 mg IM once OR Ciprofloxacin (Cipro) 500 mg orally twice a day for 3 days OR Erythromycin base 500 mg orally three times a day for 7 days	None	Azithromycin (Zithromax, Z-Pak) 1 g orally once OR Ceftriaxone (Rocephin) 250 mg IM once OR Erythromycin base 500 mg orally three times a day for 7 days	Same as for pregnant women.
Lymphogranuloma venereum	Doxycycline (Vibramycin) 100 mg orally twice a day for 21 days	Erythromycin base 500 mg orally four times a day for 21 days	Erythromycin base 500 mg orally four times a day for 21 days OR Azithromycin (Zithromax, Z-Pak) 1 g orally once a week for 3 weeks may be effective but few data on its efficacy are available.	Same as for pregnant women. Doxycycline (Vibramycin) is not an ideal treatment but may be used if risks to the infant can be minimized.
Granuloma inguinale (donovanosis) All treatments require that the medication be continued for at least 3 weeks and until the lesions completely heal	Azithromycin (Zithromax, Z-Pak) 1 g orally once per week OR Azithromycin (Zithromax, Z-Pak) 500 mg daily	Doxycycline (Vibramycin) 100 mg orally twice per day OR Ciprofloxacin (Cipro) 750 mg orally twice per day OR Erythromycin base 500 mg orally four times a day OR Trimethoprim–sulfamethoxazole 106 mg/800 mg orally two times a day	Azithromycin (Zithromax, Z-Pak) 1 g orally once per week OR Azithromycin (Zithromax, Z-Pak) 500 mg daily OR Erythromycin base 500 mg orally four times a day AND if needed Gentamycin 1 mg/kg IV every 8 hours if the woman does not improve with a few days of therapy	Same as for pregnant women. Doxycycline, ciprofloxacin, and trimethoprim–sulfamethoxazole have the potential for neonatal effects, but can be used if the infant is healthy, no other drugs are available, and risks to the infant can be minimized.

Abbreviations: IM, intramuscular; IV, intravenous.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

All women with chancroid should be screened for HIV. Women should be seen for a clinical examination 3 to 7 days after treatment initiation. The pain of the lesion and the lymphadenopathy should improve by 3 days after initiation of therapy, and the lesion should be healing by day 7 of treatment. If there is no improvement in this time frame, the woman will need a more comprehensive assessment, as outlined by the CDC.[7]

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is caused by *C. trachomatis* that is transmitted via genital or rectal mucosal contact. LGV is primarily an infection of the lymphatic system and lymph nodes. Although it is caused by *C. trachomatis*, serovars (subtypes) of the bacterium involved in LGV are different than those that cause chlamydial infection of the vagina or upper reproductive tract. Thus, LGV is a distinct disorder that differs from the more common manifestations of chlamydial infection.

Women with LGV most commonly present with unilateral, painful inguinal lymphadenopathy or pelvic pain. Approximately one-third of infected individuals remember having a nontender genital lesion. Rectal infection is becoming more common, and this location of infection can complicate diagnosis because the symptoms mimic primary care conditions—constipation, anal pain, tenesmus, and bloody and mucoid anal discharge are common.[48] Left untreated, LGV can lead to fistulas and permanent tissue damage as lymph nodes rupture and spread infection. LGV was previously rare in developed countries, but outbreaks have been increasing in recent years.[48]

Diagnosis of Lymphogranuloma Venereum

The physical examination will be remarkable for unilateral, painful, inguinal lymphadenopathy. Lymph nodes may be fluctuant and rupture on compression. The skin over the affected area may be darkened. Rectal examination reveals symptoms of proctocolitis, including inflammation of the rectal mucosa if the rectum is infected.

Laboratory tests include NAAT for *C. trachomatis* performed vaginally, rectally, or from lymph node or lesion exudate.[7] Even though laboratory tests should be performed, clinical symptoms alone can be used for diagnosis to begin treatment.[7]

Treatment of Lymphogranuloma Venereum

Pharmacologic treatment for LGV is listed in **Table 14-15**. Very large and fluctuant lymph nodes may require needle aspiration and drainage to prevent ulcerations. Nonsteroidal anti-inflammatory drugs (NSAIDs) may help mitigate pain and inflammation. All sexual partners within the 60 days prior to onset should be evaluated, tested, and treated if needed.

Granuloma Inguinale

Granuloma inguinale is rare in the United States, but is more common in low-resource tropical areas around the world. This infection is predominately transmitted through sexual contact, although nonsexual transmission may be possible. Caused by a gram-negative bacterium (*Klebsiella granulomatis*), granuloma inguinale infection begins with painless beefy-red lesions that bleed on contact. These genital lesions are progressive, spreading across the anogenital and inguinal areas. While local lymphadenopathy does not occur, subcutaneous granulomas (pseudoboboes) may form under the skin of the inguinal area. Direct testing for *K. granulomatis* is difficult even in well-supplied laboratories. Thus, diagnosis relies heavily on clinical assessment.

Diagnosis of Granuloma Inguinale

Physical examination reveals ulcerative lesions that are red and bleed easily. Lesions may also be hypertrophic or have necrotic wound portions. Local or regional lymphadenopathy and subcutaneous granulomas may be present as well. Secondary infections may cause a purulent exudate. Laboratory tests for the differential diagnosis of granuloma inguinale include HSV culture, culture for secondary bacterial infection, and dark-field microscopy for *T. pallidum*. Consider non-treponemal testing for syphilis. Because direct culture is difficult, diagnosis relies on clinical presentation and presence of risk factors for the disease (e.g., tropical location, local prevalence).

Treatment of Granuloma Inguinale

Table 14-15 summarizes pharmacologic treatment for granuloma inguinale. Treatment also includes basic wound management to treat or prevent secondary infections. Sexual partners within the previous 60 days should be evaluated and offered treatment, but the value of treatment for asymptomatic individuals has not been established.[7]

Human Papillomavirus

HPV is estimated to be the most common sexually transmitted disease; as many as half of all sexually active adults will be infected with one or more subtypes of HPV in their lifetime.[6] More than 100 subtypes of HPV have been identified to date, of which more than 40 subtypes infect the genital and potentially oropharyngeal areas. Papilloma viruses infect the surface epithelia and mucous membranes, where they cause variable cellular changes depending on the virus subtype.

Most HPV infections are asymptomatic, and 90% are eliminated by the immune system within 2 years following infection. However, certain subtypes are associated with persistent infection, leading to symptoms such as genital warts or cancers of the genitals, cervix, rectum, and oropharynx. Symptoms can appear years after the initial infection. HPV subtypes 6 and 11 cause 90% of genital warts, although subtypes 18, 31, and 33 are also found in warts. HPV subtypes 16 and 18 cause 60% to 80% of anogenital cancers, but subtype 31 is associated with anogenital cancers as well. Subtype 16 has been strongly associated with oropharyngeal cancer.[49] Warts caused by HPV subtypes 6 and 11 can also be found on mucous membranes of the mouth, nose, and eyes. This section focuses on HPV infection manifesting as growths or warts on the vulva, perineum, or anus, or within the vagina.

The path from HPV acquisition to oncogenic cell changes is complex and may be related to the individual's overall health status. Smoking increases the risk of cellular persistence of HPV and later cancer for both genital and oropharyngeal cancers.[50,51] Prolonged alcohol use is another risk factor for oropharyngeal cancer following HPV infection.[49]

Genital warts are common in the United States, accounting for hundreds of millions of dollars in healthcare expenditures annually. However, the prevalence of HPV may decrease dramatically in the next 10 to 15 years due to administration of the HPV vaccine to females and males younger than 26 years. The approved vaccines offer protection for either two, four, or nine HPV serotypes.[51]

The virus that causes genital warts is transmitted through skin and mucous membrane contact with the genitals, vulva, perineum, rectum, and—for some subtypes—oropharynx. Condoms do not thoroughly protect from genital HPV; female condoms offer some additional protection for the vulva when compared with male condoms, but do not completely eliminate the risk of infection.

Screening and Diagnosis of Human Papillomavirus Infection and Genital Warts

Screening for cervical HPV infection and cancer is part of routine health promotion, as reviewed in the *Health Promotion and Health Maintenance* chapter. Although HPV is an STI, it is impossible to determine the time of acquisition. The onset of genital warts is not a reliable indicator of either recent infection or reinfection.

Diagnosis of HPV-related genital warts occurs via physical examination, which will reveal fleshy papules or pedunculated warty lesions on the vulva, introitus, perineum, anus, cervix, and vaginal walls. Large warts, known as condylomata acuminata, may take on a cauliflower-like appearance and may bleed when abraded. These lesions may appear similar to the

condylomata lata associated with syphilis, but condylomata lata are usually flat. Warts caused by HPV turn white when exposed to acetic acid, although this test is not recommended by the CDC as a diagnostic test due to lack of specificity. Non-treponemal blood tests (RPR, VDRL) can be useful to differentiate condylomata acuminata from condylomata lata if needed.

Treatment of Genital Warts

Many genital warts resolve spontaneously and may not need treatment. The number, size, and location of warts and the cost and availability of treatments are important considerations in shared decision making.[7] All treatments for warts have localized side effects, including irritation, pain, and burning. While treatment may diminish the size and number of genital warts, it may not affect transmission rates. The woman or provider can apply treatment; self-applied medications may facilitate prolonged treatment if it is needed. Decisions about treatment should be made in partnership with the woman.

Treatments recommended by the CDC for women are presented in **Table 14-16**.[7] Podophyllin resin is no longer recommended for any woman. The CDC advises individuals to abstain from intercourse with new partners until the warts have resolved, but the person may remain contagious even after treatment. Sexual partners should be treated only if they are symptomatic and desire treatment. While pharmacologic treatments are listed in Table 14-16, surgical excision is an option if warts are extensive in any location.

Table 14-16	Pharmacologic Treatments for Genital Warts Caused by Human Papillomavirus for Women
Treatments Generic (Brand)	**Clinical Considerations**
External	
Podofilox 0.5% solution or gel (Condylox, Podofilox)	Applied by the woman twice a day for 3 days then no treatment for 4 days Useful when warts are smaller than 10 cm × 10 cm Useful when warts are smaller than 10 cm × 10 cm Maximum dose of 0.5 mL of the solution per day Demonstrate application in the office for instruction Contraindicated during pregnancy
Imiquimod 3.75% or 5% cream (Aldara)	May worsen autoimmune or inflammatory disorders Low risk for use during pregnancy but data are limited; not recommended for use during pregnancy Applied by the woman at bedtime—for 3.75% strength, apply every night for up to 16 weeks; for 5% strength, use three times a week for up to 16 weeks Wash off cream with soap and water after 6–10 hours May cause a local inflammatory response The cream may weaken latex condoms and diaphragms
Sinecatechins 15% ointment (Veregen)	Contraindicated for individuals who have herpes or HIV, or who are immunocompromised No safety data for use during pregnancy; not recommended during pregnancy Applied by the woman in a thin film over the affected area using a finger, three times a

	day for up to 16 weeks Do not wash the film off the affected area Avoid touching the skin with applied ointment to other genital, anal, or oral tissues
External	
TCA or BCA 80–90%[a]	Applied by the provider Protect areas surrounding the wart with petroleum jelly Apply acid sparingly and allow to dry, forming a white frosting Excessive acid can be neutralized with sodium bicarbonate or liquid soap Treatment can be repeated once a week Can be used during pregnancy
Cryotherapy with liquid nitrogen	Requires specialized training and equipment Performed by the provider Can be repeated every 1–2 weeks
Vaginal	
TCA or BCA 80–90%[a]	Applied by the provider Protect areas surrounding the wart with petroleum jelly Apply acid sparingly and allow to dry, forming a white frosting Excessive acid can be neutralized with sodium bicarbonate or liquid soap Treatment can be repeated once a week
Cryotherapy with liquid nitrogen	Requires specialized training and equipment Performed by the provider Can be repeated every 1–2 weeks
Urethral Meatus	
Cryotherapy with liquid nitrogen	Requires specialized training Performed by the provider Can be repeated every 1–2 weeks.
Cervical or Anal	
TCA or BCA 80–90%[a]	Intra-anal warts require specialist consultation Applied by the provider Protect areas surrounding the wart with petroleum jelly Apply acid sparingly and allow to dry, forming a white frosting Excessive acid can be neutralized with sodium bicarbonate or liquid soap Treatment can be repeated once a week Can be used during pregnancy
Cryotherapy with liquid nitrogen	Intra-anal warts require specialist consultation Requires specialized training and equipment Performed by the provider Can be repeated every 1–2 weeks

Abbreviations: BCA, bichloroacetic acid; HIV, human immunodeficiency virus; TCA, trichloroacetic acid.

[a] Acceptable pharmacologic treatment during pregnancy.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at:

https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

The need for follow-up visits is influenced by the size of lesions and the response to treatment. Warts may return following treatment and can be (re)treated with the same agent used for treating the initial infection. A biopsy is indicated if lesions have not responded after 3 months following treatment or if they are unevenly pigmented, ulcerated, or fixed.[7] Regular Pap screening according to current guidelines is important to evaluate affected women for cervical cancer, but a diagnosis of genital warts does not change regular screening frequency. Women with genital warts should be offered screening tests for common STIs.

Management of Genital Warts During the Perinatal Period

Warts may initially appear or increase in size during pregnancy. Treatment with trichloracetic acid (TCA) or bichloroacetic acid (BCA) is safe during pregnancy, but other medications used to treat HPV, such as podophyllin, are not recommended for use in pregnant women. It may be difficult to fully eliminate warts during pregnancy, and they may regress spontaneously postpartum. Surgical treatment is indicated if the warts might complicate vaginal birth.

Genital warts are highly vascularized and may bleed excessively if torn or cut during birth. Care should be taken to avoid warts during suturing of perineal lacerations following vaginal birth. Cesarean section is indicated only if extensive warts obstruct the vaginal opening or are expected to bleed uncontrollably during birth.[7]

Infants born to women with genital warts attributable to HPV subtypes 6 and 11 may develop respiratory papillomatosis—that is, warts within their airway—during the neonatal period or beyond. The mode of transmission to the fetus or neonate is not clear, and cesarean birth may not decrease the incidence of papillomatosis.[7] Some new research suggests that prenatal vaccination of the woman may reduce intrapartum fetal transmission due to antibody transfer to the fetus.[52] The infant's healthcare provider should be alerted about the potential for respiratory papillomatosis.[7]

Herpes Simplex Virus

A variety of herpes viruses affect humans. Sexually transmitted herpes infection is caused by one or two subtypes of herpes simplex virus: HSV-1 or HSV-2. These two viruses are not completely cleared from the body after the initial infection and can cause recurrent symptoms throughout life. In a large epidemiologic study of data from the U.S. National Health and Nutrition Examination Survey in 2010, the seroprevalence of HSV-1 in individuals between the ages of 14 and 49 was 53.9%. The seroprevalence of HSV-2 in this cohort was 15.7%.[53] However, in some demographic groups, the seroprevalence of HSV-2 infection in this age group was found to be close to 50%.[54] Women are more vulnerable to the HSV infection and have higher baseline rates of infection compared to men, in part due to prolonged contact with semen during vaginal intercourse.

HSV-1 and HSV-2 can cause painful ulcerations of the anogenital region and the mucous membranes of the mouth and nose. HSV-1 is commonly acquired in childhood through oral contact but can be sexually transmitted, especially through orogenital sex. In some populations, this virus is the major cause of genital herpes.[7] HSV-1 usually has a more mild clinical presentation than HSV-2, both during the first infection and subsequent outbreaks. In addition, HSV-1 is associated with lower rates of asymptomatic viral shedding.[7] HSV-2 is more often sexually transmitted and is associated with more severe symptoms and more frequent reoccurrences compared to HSV-1 infection.[7] In the United States, HSV-2 is more commonly associated with genital herpes than is HSV-1. Genital herpes infection increases the risk of acquiring HIV by fourfold, in part due to skin breaks and open lesions

Herpes is a lifelong infection that has the potential for transmission throughout the life span. Individuals can have HSV for many years before becoming symptomatic. Although an outbreak of HSV is caused by a virus that is sexually transmitted, the timing between infection and symptoms is highly variable. Furthermore, most infections of HVS-1 and HSV-2 are asymptomatic. Because HSV can be shed from asymptomatic lesions, the disorder may be transmitted to a sexual partner unknowingly. These characteristics of the viral infection can greatly complicate health education and partner counseling.

Outbreaks of HSV are commonly categorized as primary versus recurrent. The first episode of HSV (primary outbreak) is usually more severe than subsequent outbreaks. Prodromal symptoms may occur before the appearance of lesions and include tingling and burning. Constitutional symptoms can include fever, malaise, headache, and myalgia. The primary sign/symptom of the outbreak is painful lesions at the affected site. Primary outbreaks may include lesions in a wide swath or in multiple body locations; in contrast, recurrent outbreaks are usually more localized. Women may also have dysuria when urine comes in contact with an open lesion(s). All primary outbreaks should be treated to prevent prolonged or severe illness.[7] Subsequent outbreaks may be preceded by prodromal symptoms and are milder, but lesions are still painful.

Diagnosis of Herpes Simplex Virus

A woman having an HSV outbreak usually presents with small, very painful vesicles or open

lesions on the mouth, vulva, perineum, or anus. The lesions typically appear in small groups and are disproportionately painful in comparison to their size and depth. They may be fluid-filled vesicles—that is, small skin splits that are covered, oozing, crusted, or nearly healed. Edema, diffuse inflammation, and vaginal or urethral discharge may be present as well. A speculum examination may be excessively painful and is not required for diagnosis. Tender inguinal lymphadenopathy may also be present.

Diagnosis of herpes is based on physical examination confirmed with viral and serologic testing. Cell culture or polymerase chain reaction (PCR) testing of exudate from the lesion is the standard for confirmation of viral lesions. However, viral culture has low sensitivity, especially if the area is crusted over or healing.[7] Type-specific immunoglobulin G (IgG)–based assay blood testing can diagnose herpes and reveal the subtype, which is recommended by the CDC to assist in treatment decisions. The woman who has an initial herpes diagnosis should be offered testing for all common STIs, especially if she has a new partner.

Treatment of Herpes Simplex Virus

While the clinical presentation of the two subtypes is indistinguishable, the CDC recommends typing via blood testing to guide health education and treatment decisions, as HSV-2 has more virulent reoccurrences and a higher rate of transmission.[7] Serologic and viral test results are not needed to begin treatment for HSV with antiviral therapy. Treatments for initial outbreaks, episodic outbreak, and suppressive therapy are presented in **Table 14-17**.[7,55] All initial outbreaks should be treated.[7] For episodic outbreaks, medication should be started when the first prodromal symptoms are noted for best effectiveness, but treatment is beneficial even if delayed until the outbreak of lesions.[7] Suppressive treatment should be considered if recurrences are frequent or disruptive for the woman. Suppression also decreases the risk of asymptomatic shedding and transmission.[7] The woman's need for suppressive therapy may change over time and should be reevaluated periodically.[7]

Table 14-17 **Pharmacologic Treatments for Herpes Simplex Virus**

Diagnosis	Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women Generic (Brand)
Initial outbreak of HSV in an adult	Acyclovir (Zovirax) 400 mg by mouth three times a day for 7–10 days OR Acyclovir (Zovirax) 200 mg by mouth five times a day for 7–10 days OR Famciclovir (Famvir) 250 mg by mouth three times a day for 7–10 days OR Valacyclovir (Valtrex) 1 g by mouth twice a day for 7–10 days	Acyclovir has more data supporting its benefits without risks to the fetus and is preferred by the CDC. ACOG supports the use of acyclovir or valacyclovir. Severe infections should be treated with intravenous acyclovir. Acyclovir (Zovirax) 400 mg by mouth three times a day for 7–10 days OR Acyclovir (Zovirax) 200 mg orally five times a day for 7–10 days OR Valacyclovir (Valtrex) 1 g by mouth twice a day for 7–10 days	Acyclovir (Zovirax) is considered safe in breastfeeding, with drug passage to the infant being much less than newborn therapeutic doses. Lower dosages may decrease maternal serum levels, resulting in lower breast milk concentrations. Valacyclovir (Valtrex) is acceptable for use during lactation, as it is converted to acyclovir in the mother and excreted in very low amounts into breast milk. Famciclovir (Famvir) is not recommended during lactation due to lack of data.

Recurrent outbreak treatment	Acyclovir (Zovirax) 400 mg by mouth three times a day for 5 days OR Acyclovir (Zovirax) 800 mg by mouth twice a day for 5 days OR Acyclovir (Zovirax) 800 mg by mouth three times a day for 2 days OR Famciclovir (Famvir) 125 mg by mouth two times a day for 5 days OR Famciclovir (Famvir) 1 g by mouth two times 1 day OR Famciclovir (Famvir) 500 mg by mouth once, then 250 mg twice a day for 2 days OR Valacyclovir (Valtrex) 500 mg by mouth twice a day for 3 days OR Valacyclovir (Valtrex) 1 g by mouth once a day for 5 days	The CDC states that acyclovir has a better safety profile during pregnancy. ACOG supports the use of valacyclovir if needed. Acyclovir (Zovirax) 400 mg by mouth three times a day for 5 days OR Acyclovir (Zovirax) 800 mg twice a day for 5 days OR three times a day for 2 days OR Valacyclovir (Valtrex) 500 mg by mouth twice a day for 3 days OR Valacyclovir (Valtrex) 1 g by mouth daily for 5 days	See above.
Suppression of HSV outbreaks	Acyclovir (Zovirax) 400 mg orally two times a day OR Famciclovir (Famvir) 250 mg orally two times a day OR Valacyclovir (Valtrex) 1 g orally once a day OR Valacyclovir (Valtrex) 500 mg orally once a day (may be less effective than other dosing regimens)	The CDC does not have recommendations specific to pregnant women but states that acyclovir has a better safety profile. ACOG recommends: Acyclovir (Zovirax) 400 mg by mouth three times a day beginning at 36 weeks OR Valacyclovir (Valtrex) 500 mg orally twice a day beginning at 36 weeks	See above.

Abbreviation: ACOG, American College of Obstetricians and Gynecologists; CDC, Centers for Disease Control and Prevention; HSV, herpes simplex virus.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017[20]; American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 82: management of herpes in pregnancy. *Obstet Gynecol.* 2016;109(6):1489-1498.[55]

Cost and frequency of dosing are considerations when choosing a treatment for the woman with HSV-1 or HSV-2 infection. Famciclovir (Famvir) and valacyclovir (Valtrex) have greater

oral bioavailability than acyclovir (Zovirax) but are more expensive. Topical treatments are not very effective for management of initial or subsequent outbreaks. Support includes non-opioid pain management. The woman can use a peri-bottle or urinate while sitting in water in a bowl or the bathtub to decrease symptoms of dysuria.

There is limited definitive research on complimentary suppressive therapies, although l-lysine has been found not to be effective.[56] The woman can decide if the costs and side effects of such treatments are worth the personal benefit. If the woman does not improve with treatment, she may have a strain of herpes resistant to standard antiviral treatments, and viral isolate testing is needed prior to specialist consultation for further treatment.[7]

Partner treatment is not needed when a woman has HSV infection. Ideally, the woman will have an open conversation with her sexual partners about the risk of asymptomatic transmission and the need for safer sexual practices. The woman should avoid sexual contact with uninfected partners while having prodromal or outbreak symptoms, as condoms do not provide full protection from transmission. A follow-up visit is best for health education about prevention when compared to the visit for the initial outbreak. When the woman is feeling better, she will be more prepared to understand the information.

Management of Herpes During the Perinatal Period

All women should be asked if they have a history of herpes or genital lesions as part of their initial visit for pregnancy.[7] Recurrent infections during pregnancy pose little to no risk during the prenatal period, and the woman produces immunoglobulins that cross the placenta to protect the fetus from HSV. In contrast, primary outbreaks during pregnancy have been associated with a small increase in fetal abnormalities and a larger risk for intrapartum transmission.[57]

Women can be treated for herpes infections during pregnancy, as described in **Table 14-17**. Severe outbreaks with dissemination during pregnancy warrant hospitalization and treatment with intravenous acyclovir.[7] Prophylactic administration of acyclovir beginning at 36 gestational weeks has been shown to lower the incidence of asymptomatic shedding and outbreaks at term, the rate of cesarean section for HSV lesions, and the neonatal incidence of HSV.[55] Routine administration of antiviral drugs beginning at 36 weeks' gestation for women with a history of genital HSV confirmed by serologic testing is currently recommended.[55]

Pregnant women without a history of herpes whose sexual partners have herpes should be encouraged to use safe sex practices and avoid sexual contact when the partner has prodromal symptoms and/or a visible lesion. This consideration is especially important when pregnant women are close to term. In addition, women should not receive orogenital contact near their estimated date of birth if their partner has a history of oral herpes sores.

If a woman has a history of genital herpes, a careful perianal assessment is important at the first labor examination or prior to induction to rule out active infection. The greatest risk of intrapartum transmission to the infant is during a primary outbreak. Vaginal birth during a primary outbreak can have vertical transmission rates as high as 50%.[7] Vaginal birth during recurrent infections has a lower transmission rate (less than 1%), due in part to passage of

maternal immunoglobulin to the fetus across the placenta.[7] However, because morbidity and mortality are high following neonatal infection, a cesarean section should be offered if the woman has *any* active genital lesions or prodromal symptoms at the onset of labor in an area that could come in contact with the fetus during vaginal birth.[55]

If a woman has nongenital lesions when she begins labor, vaginal birth may proceed normally. All nongenital lesions should be covered with an occlusive dressing to decrease risk of transmission, especially when handling the newborn.[55] Occasionally, a woman will have a precipitous labor and give birth vaginally during a herpetic outbreak. In these cases, viral cultures of the newborn and prophylactic treatment with acyclovir may be considered, especially if this is the mother's first outbreak.[7]

The majority of newborns in the United States who develop neonatal herpes are born to women with no known history of the disease; this is due in part to increased monitoring of women with a history of herpes.[55] Approximately 85% of newborns with HSV infection contracted the virus during birth through contact with maternal secretions, whereas 10% are infected after birth via contact with infected individuals.[57] In addition, ritual circumcision with suction of the baby's blood using the adult's mouth has been shown to transmit HSV.[58] Although rare (accounting for only 5% of all neonatal cases), HSV can be transmitted across the placenta. Manifestations of this condition are similar to intrauterine varicella infection and include skin lesions, malformations of the eyes, and central nervous system dysfunction.[57]

Regardless of the route of transmission or subtype involved, HSV infection is very risky for the newborn. Symptoms of neonatal herpes usually appear on days 5 to 12 of life and include respiratory distress, irritability, jaundice, and vesicular lesions around the site of infection. Late symptoms include seizures and shock. Although neonatal herpes can remain localized to one area, there is a large risk of disseminated infection and central nervous system involvement—a condition that can lead to mortality rates as high as 85% without treatment.[57] Early treatment with antiviral agents can reduce this risk of death to 29%.[57] The pediatric provider should be notified immediately following the birth if a newborn may have been exposed to HSV during the birth.

HSV is communicable only through contact with infected secretions from mucous membranes of the mouth or genitals. Women with HSV should be encouraged to breastfeed unless there is a herpetic lesion directly on the nipple.[55]

Hepatitis

Hepatitis is a small double-stranded DNA hepadnavirus. Eight genotypes of hepatitis viruses (A–H) have been identified, all of which have been found in the United States. Nevertheless, hepatitis A, B, and C are the most prevalent types in the United States. The hepatitis viruses primarily attack the liver and cause acute and/or chronic hepatitis. Chronic infection can lead to cirrhosis, hepatocellular carcinoma, and death.

Hepatitis viruses can be acquired in different ways. Hepatitis A virus (HAV) is primarily transmitted via fecal–oral contact and is reviewed in the *Common Conditions in Primary Care* chapter. Hepatitis B (HBV), C (HCV), and D (HDV) are transmitted via blood and bodily secretions, including semen and (rarely) saliva. Such transmission may occur during sexual contact (genital and oral), during birth, through needle-sticks or sharing of needles, and with use of nonsterilized instruments. Thus HBV, HCV, and HDV infections are considered STIs.

Hepatitis B

More than 240 million people worldwide and 2.2 million people in the United States are chronically infected with the hepatitis B virus (HBV).[59,60] HBV can remain infectious outside the body for several days, even if dry, and is able to establish infection with very few initial organisms, making it highly infectious.[59] In addition, HBV has numerous components that are antigenic, including the surface antigen (HBsAg), core antigen (HBcAg), and e antigen (HBeAg). The chance of transmission of HBV depends on the infected individual's viral load and antigen status (a marker of high infectivity).

HBV can become a chronic infection that causes cirrhosis, liver cancer, and death. The chances of chronic infection vary by age at the time of initial infection. For example, 90% of infants who acquire HBV via mother-to-child-transmission at the time of birth will develop chronic infection, compared to 5% or fewer of persons who acquire the disease during adulthood.[61] Global rates of chronic infection are higher in part because of the impaired immune response associated with coinfection with HIV and tuberculosis.[59]

HBV infection is often asymptomatic, or symptoms may be vague enough to go unnoticed. This disease typically has an incubation period of 60 to 90 days. The prodromal phase lasts 3 to 10 days, during which commonly noted symptoms include fatigue, nausea, and diffuse epigastric or right upper quadrant pain. This is followed by an icteric phase of 1 to 3 weeks that is characterized by symptoms such as jaundice, dark urine, and gray stools. Convalescence can take weeks to months.

Prevention of Hepatitis B

In the United States, the overall rate of HBV infection has declined more than 80% since 1991, when the CDC began a campaign to reduce HBV prevalence.[60] The HBV vaccine is produced from derivatives of yeast, without the use of blood products, so it cannot cause hepatitis.[7] Vaccination is recommended for several at-risk groups, as described in the *Health Promotion*

and Health Maintenance chapter.[7,59] The vaccine dose varies based on the reason for vaccination, with immunocompromised adults receiving larger doses. Individuals should receive all doses from the same vaccine manufacturer.[7]

Routine screening of pregnant women and immunoprophylaxis of all newborns of infected mothers have also been useful in decreasing the prevalence of chronic hepatitis in the United States.[60] Other preventive strategies include universal precautions, careful instrument sterilization, safer sex practices, and not sharing toothbrushes and razors with infected individuals.[7,59]

Postexposure Immunoprophylaxis.

Postexposure prophylaxis decreases rates of acute and chronic infection but is most useful if prophylaxis is administered within 24 hours of exposure.[7] If an individual who has not been previously vaccinated, or who is not fully vaccinated, is exposed to HBV, administration of the HBV vaccine at the same time (different injection sites) as hepatitis B immunoglobulin (HBIG) has been shown to reduce transmission.[7] The vaccine series should then be completed using the CDC age-appropriate dose and schedule. Information about postexposure prophylaxis resources for viral blood-borne infections can be found in the Resources section at the end of this chapter.

Screening and Diagnosis of Hepatitis B

Screening for HBV occurs via serologic testing for hepatitis B surface antigen (HBsAg). If the woman is HBsAg positive, a complete hepatitis panel can be obtained to determine acute versus chronic status. This panel includes the hepatitis B e antigen (HBeAg), which is a marker of a high degree of infectivity; IgM anticore antibody (IgM anti-HBc), which is a marker of recent infection within the last 6 months and indicates acute infection; IgG anticore antibody (IgG anti-HBc), which is a marker of past or current infection; antihepatitis B surface antibody (anti-HBs), which is a marker of an immune response to HBV; antihepatitis B e antigen (anti-HBe), which may be present in a person who is either infected or immune; and viral load, which reveals the concentration of the hepatitis B virus DNA within the blood.

Diagnosis is based on interpretation of hepatitis serology, as shown in **Table 14-18**[7,62] and **Figure 14-3**.[65] Physical examination findings during acute HBV infection include upper abdominal tenderness, hepatomegaly, and, occasionally, jaundice. Women with hepatitis may also exhibit other abnormal serum tests, including elevated aspartate aminotransferase (AST), elevated alanine aminotransferase (ALT), elevated bilirubin, and a prolonged prothrombin time.

Table 14-18 **Interpretation of Hepatitis B Serology**

Interpretation	HBsAg	HBeAg	IgM Anti-HBc	Total Anti-HBc	HepB Serum Titer	Anti-HBe	Anti-HBs
Never infected (susceptible)	–	–	–	–	–	–	–
Early acute or immediately after vaccination[a]	+	–	–	–	Variable	–	–
Acute	+	+	+	+	High	–	–
Resolving acute	+	–	+	+	Low	+ or –	–
Chronic	+	+ or –	–	+	High or low	+ or –	–
Resolved (immune)	–	–	–	+	–	+ or –	+
Vaccinated (immune)	–	–	–	–	–	–	+
False positive[b]	–	–	–	+	–	–	–

Abbreviations: anti-HBe, antihepatitis B e antibody; anti-HBs, antihepatitis B surface antibody; FDA, U.S. Food and Drug Administration; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HepB, hepatitis B; IgM Anti-HBc, IgM antibody to hepatitis B core antigen; +, positive; –, negative.

[a] The HBsAg test can lead to false positive because it can react to other viral antigens. To ensure that a positive HBsAg is not a false positive, samples that are positive should be tested with an FDA-cleared test for HBsAg only.
[b] If the anti-HBc is positive and other hepatitis serologies are negative, it is unlikely the person is infected, except in case of previous blood transfusion or organ transplantation.

Treatment of Hepatitis B

All cases of newly diagnosed hepatitis B should be reported to the local health department. If a woman has hepatitis B, her household contacts should be vaccinated, and her sexual partner tested and vaccinated if not infected.[64] There is no specific treatment for adults with acute hepatitis, other than a supportive lifestyle to assist the body in healing.[7]

Individuals who are chronically infected can receive treatment to decrease the risk of liver disease,[7] and should be referred to providers knowledgeable in the management of hepatitis and chronic liver disease.[7] The woman can benefit from specialist referral for guidance about lifetime lifestyle modifications to decrease liver injury (e.g., avoidance of acetaminophen and alcohol).

Management of Hepatitis B During the Perinatal Period

Serologic screening for HBsAg is routinely included as one of the initial laboratory tests for all pregnant women during each pregnancy.[64] Hepatitis B vaccination is safe during pregnancy and appropriate for women at risk. Pregnancy is a good time for vaccination of at-risk women, as they are already in the clinic at the appropriate intervals.[64] **Figure 14-4** presents an algorithm for screening and referral for pregnant women with HBV.[64,65]

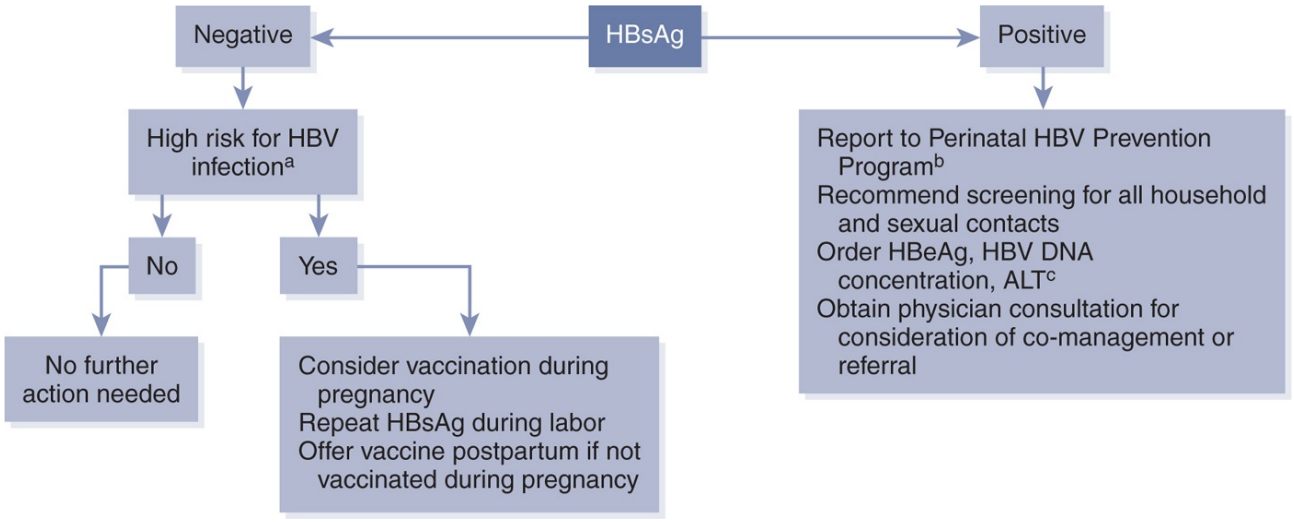

Figure 14-4 Screening and referral algorithm for hepatitis B virus infection among pregnant women.

Abbreviations: ALT, alanine transaminase; DNA, deoxyribonucleic acid; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HIV, human immunodeficiency virus.

[a] High risk for HBV infection includes household or sexual contacts of HBsAg-positive persons, injection drug use, more than one sex partner during the last 6 months, evaluation for or treatment of a sexually transmitted infection, HIV infection, chronic liver disease, or end-stage renal disease, and international travel to regions with HBsAg prevalence of more than 2%.

[b] The Centers for Disease Control and Prevention coordinates and funds state, local, and territorial programs that focus on preventing hepatitis B virus transmission from pregnant women to their newborns. Local reporting guidelines can be found at https://www.cdc.gov/hepatitis/partners/perihepbcoord.htm.

[c] If HBeAg positive or HBV DNA > 20,000 IU/mL or ALT ≥ 19 IU/mL, immediate referral to specialist for care during pregnancy is recommended.

Based on Centers for Disease Control and Prevention, American College of Obstetricians and Gynecologists. Screening and referral algorithm for hepatitis B virus (HBV) infection among pregnant women. 2015. Available at: https://www.cdc.gov/hepatitis. Accessed March 31, 2017.*64*

Women who are acutely infected with HBV may need additional care if they have severe symptoms, have high levels of HBV in their blood, have elevated alkaline aminotransferase levels, or show signs of coagulopathy or encephalopathy.[64,66] Viral load is an important component of management. Women with high viral loads (more than 6–8 log 10 copies/mL) can benefit from specialist involvement and antiretroviral medications during the third trimester,[67] but pregnancy does not change the course of HBV infection for most women.[66,68]

Treatment of HBV during pregnancy is primarily directed toward decreasing the risk of vertical transmission. Although current guidelines do not recommend treatment during pregnancy for all women with chronic HBV,[66] recent studies have shown that treatment of chronic HBV during pregnancy decreases the risk of vertical transmission; as this research matures, universal treatment may become recommended.[69]

The risk of vertical transmission increases with viral load and type of antigen present. Women who are HBsAg positive as well as HBeAg positive are at the greatest risk for vertically transmitting the virus, and should be referred for a specialist consultation to make a decision about treatment during the third trimester of pregnancy.[64,66,70] Invasive genetic testing can be offered to HBsAg-positive women, but vertical transmission is increased with high viral load counts at the time of the procedure.[67] The woman's chart should note her HBsAg status, and this information should be conveyed to the woman's chosen birth location to allow preparation for HBIG administration to the newborn following birth.

Intrapartum management of women infected with HBV is the same as that offered to women who are not infected with HBV. Hepatitis status should not influence the preferred route of birth (vaginal or cesarean section). However, because fetal scalp electrodes may increase the risk of neonatal infection, an electrode should be applied only if the benefits outweigh the potential risks.

The CDC advises routine HBV vaccination of all infants weighing more than 2000 g, regardless of the mother's HBV status.[71] Newborns of women infected with HBV should be given HBIG and their first hepatitis vaccine within 12 hours of birth.[71] Removal of maternal blood from the infant's skin or bathing of the infant soon after birth is also recommended to decrease neonatal contact with maternal blood.[63] The CDC is an excellent resource for comprehensive information about prevention of perinatal transmission of hepatitis B and provides health education information in a variety of languages.

Hepatitis B is *not* transmitted through breast milk, and women should be encouraged to breastfeed regardless of their hepatitis B status.[7] While transmission of HBV from women with cracked or bleeding nipples has raised some concerns, there is no conclusive evidence of transmission by this route. Breastfeeding should not be interrupted for this reason.[67]

Hepatitis C

Risk factors for HCV include nonsterile tattooing, blood transfusion before 1987, organ transplant before 1992, HIV-positive status, STIs, multiple sexual partners, evidence of liver disease, and a history of long-term hemodialysis.[72] The primary risk factors for HCV in the United States are use of blood products and illicit intravenous drug use. Compared to HBV, HCV is much less likely to be transmitted via sexual contact or via mother-to-child-transmission during birth, although transmission can occur through these routes.

The CDC recommends that all individuals with risk factors and persons born between 1945 and 1965 be tested for HCV.[7] Several forms of HCV exist, and knowing the genotype informs treatment.[72] Approximately 75% to 85% of persons with HCV will develop chronic infection, and HCV is one of the leading causes of liver cancer.[72] The U.S. Food and Drug Administration (FDA) has approved several drugs for treatment of HCV. Women with acute HCV should be referred to a specialist for care.

Management of Hepatitis C During the Perinatal Period

Women at risk for HCV should be offered screening during pregnancy, but universal screening during pregnancy is not recommended at this time.[66,73] However, as the incidence of HCV in the United States has risen in recent years in concert with the increased use of opioids, universal screening for HCV may become recommended in some geographic areas.[73,74] The risk of transmitting HCV to the fetus during birth is approximately 6%; at this time, there are no treatments proven to prevent mother-to-child-transmission.[75] Treatment of acute HCV during pregnancy may require hospitalization and physician care, but there is no standard treatment for chronic HCV at this time. Women with chronic HCV may breastfeed. Midwives, in consultation with obstetric specialists, can manage care for women with chronic HCV.

Hepatitis D

Hepatitis D is an incomplete RNA hepatitis viral particle that causes disease only in the setting of chronic HBV infection. Hepatitis D can obtain a viral envelope composed of HBsAg when in the presence of HBV, thereby becoming communicable and presenting as coinfection. HDV is primarily transmitted via blood. This hepatitis variant is associated with more severe disease and more rapid progression to cirrhosis, as compared to other hepatitis variants.

Persons with chronic HBV should be tested for HDV. If present, the individual will be treated for HBV and require specialist care. The hepatitis B vaccine also confers protection against HDV.

Human Immunodeficiency Virus

The human immunodeficiency virus is an RNA retrovirus (i.e., an RNA virus that replicates via production of DNA that is inserted into the host cell genome) that is transmitted through infected blood and bodily secretions. The CDC estimates that 50,000 individuals contract HIV in the United States every year, and 250,000 individuals have undiagnosed HIV infection. In the United States, HIV is most commonly transmitted through sexual intercourse. Exposure to infected blood through sharing of infected needles or accidental needle-sticks and other mechanisms are additional routes of transmission. Pre-exposure prophylaxis is available for those persons at high risk for HIV acquisition, and postexposure prophylaxis can be used within 72 hours of an exposure to prevent HIV acquisition.

The risk of acquisition of HIV during sex is greatly increased if a woman has other STIs, such as herpes, gonorrhea, or STIs causing genital ulcers that facilitate access to the circulation. Sexual practices that are more damaging to the vaginal and rectal mucosa also increase the risk of contracting HIV.

HIV proceeds through several stages after infecting the immune system's CD4 cells (a type of T cell). The first stage, called acute retroviral syndrome, occurs within the first few weeks after infection. It is characterized by fever, malaise, a skin rash, nausea or diarrhea, headache, sore throat, and lymphadenopathy—symptoms that are much like those associated with mononucleosis.[7] The symptoms of acute retroviral syndrome can be mild or severe. The infection then becomes asymptomatic during a period of clinical latency that can last a short time or up to 8 years or longer, depending on the individual. During this time, HIV reproduces at very low levels, although it is still active. When the CD4 cell count falls below 200 cells/mm^3, symptoms of advanced infection or acquired immunodeficiency syndrome (AIDS) appear. Symptoms of AIDS include fever, weight loss, diarrhea, cough, shortness of breath, opportunistic infections, and more intense illnesses and infections more severe than would be expected for the woman's age or health status.[7]

In late stages of untreated HIV infection, the number of functioning CD4 cells decreases as viral replication kills the host cells, rendering the woman susceptible to a wide variety of opportunistic infections. Presenting symptoms may include vulvovaginal or oral candidiasis, shingles, abnormal Pap tests, and STIs. In addition, HIV infection makes women more susceptible to cancer. Once the CD4 count falls below 200 cells/mm^3, the woman is likely to develop a variety of opportunistic infections, which collectively define the onset of AIDS.[7] However, with current treatment, HIV infection can be successfully managed, vastly improving long-term health outcomes.

Two types of HIV viruses exist: HIV-1 and HIV-2. The vast majority of HIV infections in the United States and worldwide are caused by the HIV-1 virus. HIV-2 is predominately found in West Africa, but this subtype is now becoming more common globally.[7] Both types of HIV produce similar symptoms and effects within the body, but their infectivity and treatment vary. Initial screening tests for HIV are able to detect antibodies to both HIV-1 and HIV-2, and further tests can differentiate the viruses (see **Figure 14-5** later in this section).

Prevention of HIV Infection

Strategies to prevent HIV transmission range from behavioral to pharmacologic in nature. Methods to prevent transmission can be customized, based on HIV status and sexual behaviors, for the woman and her partner(s).[75,76] The CDC has an excellent, interactive risk reduction tool that can be found in the Resources section at the end of this chapter. Women at high risk for HIV acquisition may also benefit from pre-exposure or postexposure prophylaxis[75,76]

Pre-exposure Prophylaxis

Pre-exposure prophylaxis (PrEP) has been shown to reduce the risk of HIV acquisition by as much as 92%.[77] PrEP is appropriate for any adult woman at high risk for HIV infection, including women who use intravenous drugs and have been in drug treatment, share injection equipment, or have an HIV-positive drug-injecting partner. Women who have sex with men and have had a recent bacterial STI, infrequently use condoms with one or more nonmonogamous sexual partners at risk for HIV (including a male who also has sex with males), engage in commercial sex work, or live in a high-prevalence geographic area should also be counseled about PrEP availability and effectiveness.

Prior to beginning PrEP, women should be tested for HIV, renal function, and hepatitis B and C.[76] If indicated, women should be offered vaccination for hepatitis B.[71] Women also need a method of contraception while taking PrEP.[75] All contraceptives can be used while taking antiviral medications, although fosamprenavir may have some drug interactions with contraceptives.[78]

If a woman who is HIV negative has a male sexual partner who is HIV positive and wishes to conceive, guidance for reproductive options is available on the CDC website, and specialist referral is appropriate.[79] PrEP use during pregnancy is still under study.[79] Specialist input is valuable for planning care during pregnancy, as risks and benefits of PrEP depend on several factors as well as maternal preference.

Once the woman is appropriately screened, PrEP involves a once-daily oral combination of 300 mg tenofovir disoproxil fumarate and 200 mg emtricitabine (Truvada). This regimen decreases the chance of HIV acquisition, but the woman should continue safer sex practices. While receiving PrEP, the woman needs to visit every 3 months for HIV and pregnancy testing and continued health education on risk reduction; renal function should be tested at 3 months, and then every 6 months.[77] Specialist involvement is ideal when possible, but should not delay access to PrEP when needed. The CDC website provides more information.

Postexposure Prophylaxis

Postexposure prophylaxis (PEP) differs depending on the origin of the exposure: occupational or non-occupational. When a healthcare provider is exposed to potentially infectious fluids, HIV testing should ideally be performed on the source individual (with her or his consent), and then a plan for care quickly formulated using expert consultation or the current information on the CDC website.[80,81] PEP for HIV is time sensitive and should occur within 72 hours of

exposure.[79]

Non-occupational exposure to HIV-infected fluids through sex, assault, or injection drugs also needs rapid attention (e.g., an expedited clinic appointment). Exposed individuals should receive a comprehensive assessment, including information on the exposure as well as the HIV status of the source individual. If the source individual is not known to be HIV positive, administration of PEP should be determined on an individual basis, with the woman receiving health education about the risks and benefits of each approach so she can participate in shared decision making. The risk for HIV acquisition depends on the source fluid (blood, semen, other bodily fluids) and the site of fluid contact. In addition to HIV counseling, the shared decision-making process should also consider the woman's risk for other STIs as well as hepatitis B and C acquisition.

The CDC has comprehensive information on baseline testing and PEP regimes for HIV and other infections.[82] Emergency contraception should also be offered when appropriate, as detailed in the *Family Planning* chapter.

Screening and Diagnosis of HIV Infection

Midwives are often involved in screening and diagnosis of HIV infection. Such screening should be offered in the same manner as any test. Consent for HIV testing can be included within a larger consent for all health care; a special HIV testing consent form is not needed and may act as a barrier to screening. HIV testing should be presented as the norm, and women allowed to opt out without coercion if they do not wish to be tested.[7]

Routine HIV screening should be offered to all women at risk for STIs, and annual screening provided to women at high risk, as reviewed in the *Health Promotion and Health Maintenance* chapter. An algorithm for interpretation of HIV tests is found in **Figure 14-5**.[83] As many as 16% of persons who are HIV positive do not know their HIV status.[7] Pregnant women should be screened at least once during pregnancy using an opt-out approach, and another HIV test should be considered in the third trimester.[7] Many states require third-trimester testing for all pregnant women, unless they opt out of screening.[7] State requirements can be found on state health websites and in CDC's HIV online resources.

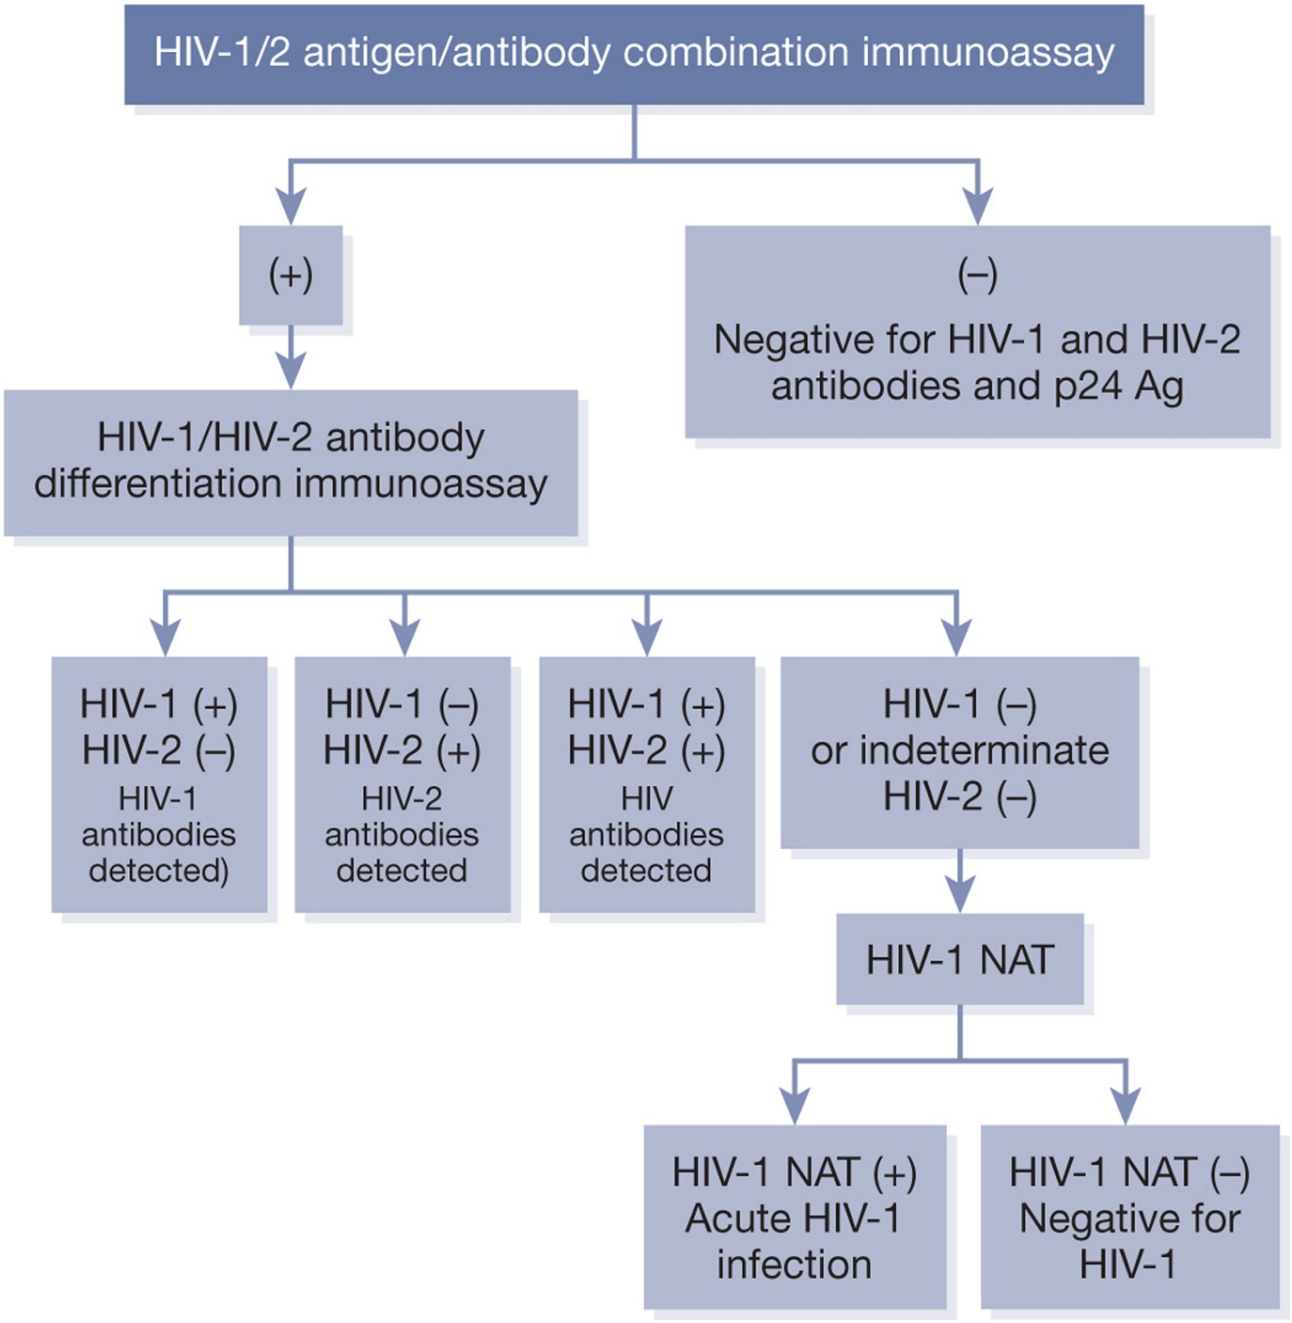

Figure 14-5 Recommended laboratory HIV testing algorithm for serum or plasma specimens.

Most of the commonly used screening tools detect antigens or antibodies to HIV, rather than the presence of the virus itself, and are appropriate first tests for most individuals. Antibodies appear 2 to 12 weeks after infection occurs. Routine screening can be performed with in-office test kits using oral fluids, blood, or serum or with laboratory testing on blood specimens. In-office rapid testing allows provision of results in 20 minutes. The most commonly used

laboratory screening test is a conventional/rapid EIA. More rarely, a CLIA may be used. The provider should select the one that screens for both HIV-1 and HIV-2.[83] Note that if an individual is newly infected (as would be the case if a woman presents with acute retroviral syndrome), these antigen/antibody tests can provide a false-negative result, as they do not detect the actual virus.

All of the screening tests for HIV have a risk of false-positive results. Therefore, if a screening test is positive, it is repeated. If both tests are positive, a diagnostic test is performed to ensure the person has HIV infection. Appropriate supplemental tests for confirmation of HIV-positive status include HIV-1/HIV-2 antibody differentiation, Western blot testing, and indirect immunofluorescence assay. A positive supplementary test, such as Western blot, indirect immunofluorescence assay, or HIV RNA assay, provides the definitive diagnosis of HIV infection. If the confirmatory test is indeterminate, an HIV RNA test is performed.[83] Reporting to public health authorities is mandated when HIV infection is diagnosed, but not when a screening test is positive.[83]

If a woman has had a recent exposure to HIV and is experiencing symptoms of acute retroviral syndrome (fever, malaise, lymphadenopathy, and skin rash), she should be tested using an HIV-1 RNA assay and an antibody test. Home HIV-testing kits detect antibodies that are not present during the acute phase. Diagnosis during this initial phase is important, however, because the person is highly infectious and prompt treatment can decrease viral spread and may improve outcomes.[7]

Negative HIV test results can be conveyed by phone, but positive results should be given to the individual in person, if at all possible. At the time of diagnosis, it is best to provide contact information for a clinic, physician, or healthcare team who can offer ongoing care. In the past, an HIV diagnosis was often perceived as a death sentence, but today this infection is managed like a chronic condition needing ongoing treatment and care. Even so, HIV infection still carries significant stigma and fear. Telling a woman she has HIV infection is difficult even for experienced clinicians.

Proper preparation prior to the visit can be helpful. Often, local or regional organizations provide specific behavioral and psychological services for HIV-positive individuals and can be contacted to provide information prior to meeting with the woman. The midwife should gather needed written materials to supplement the conversation and provide the woman with reference materials in case she cannot remember the full details of the conversation. Midwifery presence and therapeutic communication skills are useful in providing an honest diagnosis while remaining compassionate and adjusting the information to the woman's needs. Similar to providing information about other STIs, the midwife should provide the woman with the diagnosis and allow her time to react and formulate questions.

The CDC recommends that a diagnosis of HIV infection be provided in conjunction with key health education points, listed in **Table 14-19**. Essential health education points should be discussed verbally and reinforced with written materials. All women with a new diagnosis of HIV should also be screened for intimate-partner violence and a discussion of how to disclose HIV status to sexual partner(s) should be explored.[84] If the woman is at risk for intimate-partner violence, resources and ways to assure safety are a priority for this visit. Information about disclosure to a sexual partner, safe sex practices, risk reduction, PrEP, and PEP can be

found on the CDC website, and the health department's partner services can be helpful as well.[85] The information provided should be compatible with the woman's educational level, culture, and desire for knowledge; health education can be prioritized if the woman appears to be overwhelmed or disinterested.

Recommendations for HIV prevention with adults and adolescents with HIV in the United States, 2014: summary for clinical providers. 2014. Available at: http://stacks.cdc.gov/view/cdc/26063. Accessed March 31, 2017.[86]

Treatment of HIV Infection

Midwives should refer all women with a new HIV diagnosis to appropriate local or regional specialists and verify that these individuals have initiated care.[7] Treatment for HIV infection is dependent on the woman's current health status, including her viral load and comorbid disorders. Referral to an HIV specialist allows the woman to receive optimal care.[86]

Although the majority of midwives in the United States do not routinely care for HIV-positive individuals, some do work in multidisciplinary teams to provide holistic and comprehensive care to HIV-positive women during pregnancy and across the life span. Midwives in these settings collaborate with, consult with, or refer to a variety of healthcare providers to ensure women with HIV infection receive care at facilities that are accessible, are acceptable, and provide evidence-based care.

Women who are HIV positive, who are sexually active, and who do not desire pregnancy need contraception. While condoms are an essential part of safer sex practices, their effectiveness in prevention of pregnancy may not be adequate. The WHO and CDC eligibility

criteria list a variety of contraceptives that are safe with HIV infection, and the CDC recommendations can be accessed via a smartphone app. All contraceptive methods, other than spermicides, are acceptable for clinically well women receiving antiretroviral treatment. If the woman is not receiving treatment or is ill, the IUD may not be an ideal choice, but can be used.[78] Spermicides are implicated in STI acquisition and are not very effective in pregnancy prevention, so their use is not advised.[87] If an HIV-positive woman wants to conceive, preconception planning is essential to optimize her own health, avoid birth defects from teratogenic medications, and prevent transmission of HIV to her partner and fetus.

Women with HIV infection face a wide range of potential sequelae from this infection. Because HIV cannot be eradicated from the body, infection is lifelong. Treatment to prevent immune system depletion and opportunistic infections is ongoing and requires close collaboration between the woman and her healthcare team. Preventive care, including Pap tests and physical examinations, is more frequent for HIV-positive women due to increased susceptibility to infections and cancer.[7]

Management of HIV Infection During the Perinatal Period

All women should be offered screening for HIV early during pregnancy and, ideally, again in the third trimester. There are wide racial health disparities in vertical transmission in the United States, and ensuring women are tested and then welcomed into woman-centered, affirming, and culturally appropriate care is essential in reducing these disparities.[88]

Women who are HIV positive should receive enhanced prenatal care. They can benefit from ancillary counseling and services in addition to traditional prenatal care. While pregnancy does not affect HIV progression to AIDS, HIV infection has been associated with poor perinatal outcomes, especially in low-resource areas of the world.[89]

Early and consistent antiretroviral treatment is an essential component of HIV management during pregnancy and prevention of vertical transmission.[90] Women with HIV infection need an early ultrasound to confirm their due date because a scheduled cesarean section before labor is an option for decreasing vertical transmission. Noninvasive testing for fetal anomalies is appropriate at the same intervals as for women who are HIV negative. Invasive fetal testing, such as amniocentesis, is reserved for situations where noninvasive testing has shown abnormalities.[90]

Prenatal care for women with HIV infection should also involve practitioners skilled in HIV management and pregnancy care. Ideal care involves multidisciplinary collaboration between clinicians and behavioral and psychological health professionals. Midwives can be a component of this care, but the knowledge needed for HIV management is beyond the American College of Nurse-Midwives' Core Competencies. If advanced skills are practiced, they should be added to practice guidelines using the procedures outlined in the Standards for the Practice of Midwifery.[91] Assessment of viral load at term is indicated to determine the ideal route of birth. Cesarean section prior to the start of labor for all women with a viral load of more than 1000 copies/mL is recommended.[7] The combination of antiretroviral medications and cesarean birth for women with a high viral load has reduced vertical transmission from rates as high as

25% to 2% or less in the United States.

Women who have not been screened during pregnancy or women at risk for HIV infection without a third-trimester screening should be screened while in labor. A rapid test is appropriate, as it will yield results in time to begin intrapartum interventions to decrease transmission. While a positive rapid test warrants intrapartum treatment, a set of full screening and diagnostic tests should be performed for definitive diagnosis.[7]

If a laboring woman is HIV positive, or suspected to be HIV positive, antiretroviral medications should be initiated. If the woman's viral load is known to be more than 1000 copies/mL, a cesarean birth following several hours of antiretroviral treatment decreases the risk of vertical transmission.[90] If a vaginal birth is planned, it is appropriate to minimize risk to the infant by facilitating a physiologic birth. Fetal scalp electrodes, episiotomies, and forceps/vacuum-assisted birth are associated with increased transmission to the fetus and should be avoided.[90]

Newborns should be treated with antiretroviral therapy as soon as possible after birth, preferably within 6 to 12 hours of birth.[90] Oral zidovudine (AZT, Retrovir) is the drug of choice for term infants whose mother received prenatal prophylaxis with antiretroviral agents. Guidelines call for zidovudine treatment to continue for 6 weeks.[90] Consultation with pediatric care providers or infectious disease specialists is appropriate. Newborns of mothers treated with antiretroviral medications can develop a variety of problems, including anemia, jaundice, and birth defects, and need evaluation by clinicians experienced in HIV care.

Breastfeeding exposes the infant to HIV through breast milk and can transmit the virus. In areas where safe breast milk substitutes are consistently available, breastfeeding is not recommended. This is the case in the United States and throughout the developed world; the CDC recommends that HIV-positive women in the United States do not breastfeed their infants.[7]

Worldwide, however, the majority of cases of HIV/AIDs occur in areas where safe breast milk substitutes are not reliably available. Infants and children fed breast milk substitutes in these areas may have higher rates of morbidity and mortality when compared with their breastfed peers. In these circumstances, the risk of death from other infections, especially diarrheal illness, is higher than the risk of HIV acquisition from breastfeeding, especially if the mother is taking antiretroviral medication.[92] Local or country-level health officials should decide whether the breastfeeding benefits outweigh the risks in their particular area.[92]

If the child is already known to be HIV positive, he or she should be breastfed as long as the mother and infant desire. However, if the infant is HIV negative or has an unknown HIV status, the risk of HIV acquisition through breastfeeding accumulates as the infant ages. The mother's viral load and CD4 count play a role in maternal–child transmission of the virus, and antiretroviral therapy decreases transmission through breast milk. The mother's personal health, her environment, and the availability of safe feeding alternatives influence the decision of when to wean the infant.[92]

Zika Virus

Zika virus is the most recent virus identified as being transmitted via sexual activity. Zika is a single-stranded RNA arbovirus related to yellow fever and dengue. The virus is transmitted by the bite of *Aedes* species of mosquitos, maternal-to-child transmission, blood transfusion, or sexual contact. Most Zika virus cases are found in the southeastern portion of the United States, and in several nations in Southeast Asia and South America.[93]

Zika virus infection is generally mild and self-limited. The incubation period is approximately 3 to 12 days, and viremia lasts for several days to 1 week. However, during pregnancy, this virus can cross the placenta and infect the cells of the fetus's central nervous system. Zika infection during pregnancy is associated with microcephaly, ventriculomegaly, ophthalmologic abnormalities, intrauterine growth restriction, and stillbirth.[94] Active surveillance and research into Zika infection are being conducted, and the pathologic features of this virus continue to be the subject of investigation. The estimated risk of vertical transmission appears to be low (0.5%),[95] but the incidence of any birth defect or abnormality in the fetus is in the range of 5% to 40% if Zika infection is confirmed during pregnancy. The factors that affect transmission are largely unknown.

There is no vaccine and no antiviral prophylaxis therapy that prevents Zika infection at this time. Zika virus disease is a reportable disorder in the United States. Suspected or confirmed cases of Zika infection should be reported to the health department. Information about prevention, travel recommendations, and treatment can be found on the CDC website.

Pregnant women should avoid travel to areas in which Zika virus has been identified, use preventive measures to avoid mosquito bites, and use condoms if their sex partner lives or travels to an area where the Zika virus is present. The CDC maintains guidelines for screening of women who are not pregnant and women who are pregnant based on travel or residence in an area associated with Zika virus, reported exposure, and symptoms. These guidelines are updated frequently.[96,97] Physician consultation should be obtained for any woman who reports a risk of being exposed to this virus.

Treatment of Zika virus disease is supportive. In pregnant women, care is focused on surveillance for vertical transmission and fetal effects. Healthcare workers should follow universal precautions to protect against exposure to body fluids.[98] More information can be found on the CDC website listed in the Resources section at the end of this chapter.

Protozoal and Parasitic Infections

Several organisms classified as protozoans or parasites can cause reproductive tract infections. Trichomoniasis is the most common protozoan-related STI. Lice are parasitic organisms that may infect the head, body, or pubic area depending on the type of louse. Specifically, *Pthirus pubis* is the type of louse that infects the pubic area. Although *Pthirus pubis* is commonly spread via sexual contact, this organism can be transmitted via contact with linen or other objects. Although infections with the parasites scabies and *Molluscum contagiosum* are not traditional STIs, these organisms are often transmitted via sexual contact.

Trichomoniasis

Trichomoniasis, commonly known as “trich,” is a vaginal or urethral infection caused by the protozoa *Trichomonas vaginalis* (**Figure 14-6**). The pear-shaped protozoa have five flagella and are highly motile. They are transmitted through sexual contact, which transfers infected secretions to the urethra and vagina. Fomites are a possible, but unlikely, mechanism of infection, as trichomonads must be kept moist and warm. More than 2.3 million women in the United States have trichomoniasis at any given time; in some populations, 13% of women are infected.[7] *Trichomonas* infection is not required to be reported, however, so incidence/prevalence estimates lack precision. Trichomoniasis is associated with increased risk for preterm birth and a three-fold increase in risk of HIV acquisition.[7]

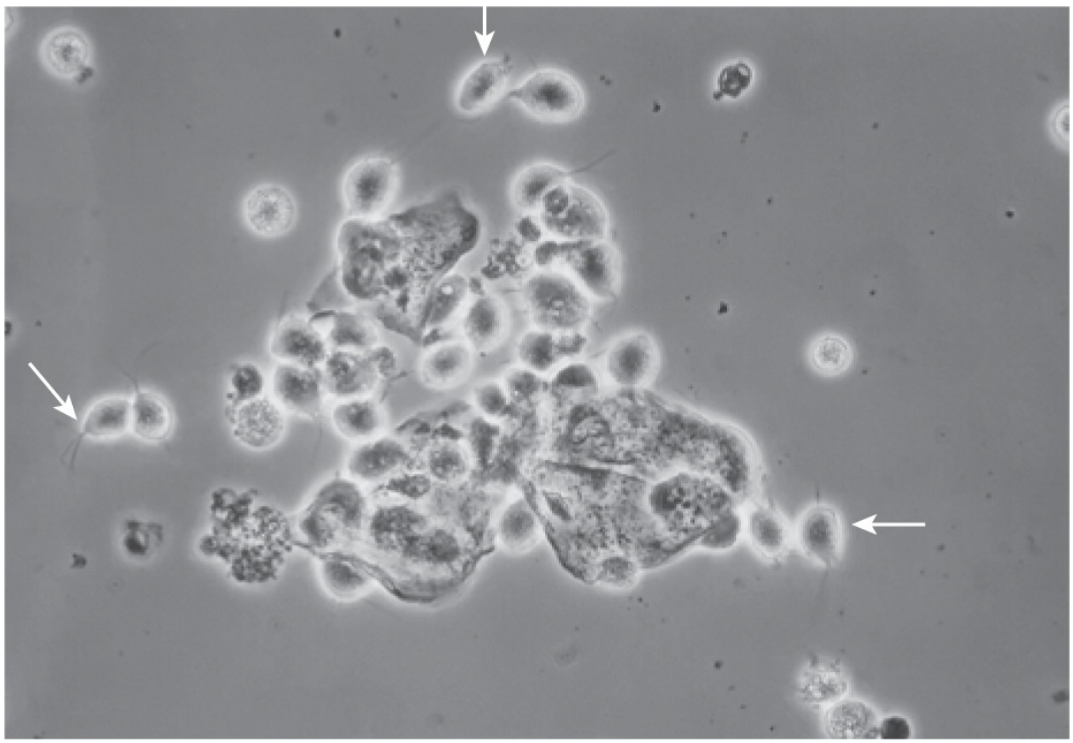

Figure 14-6 Trichomonas.

Courtesy of CDC/Joe Miller.

Trichomoniasis is frequently asymptomatic. Symptoms, when present, include vaginal itching, irritation, and malodorous vaginal discharge. Abdominal discomfort may also be present.

Screening and Diagnosis of Trichomoniasis

Routine screening for trichomoniasis is recommended only for women who are HIV positive because this coinfection is associated with an increased risk for PID. This recommendation applies to both nonpregnant and pregnant women. Routine screening and treatment have not been shown to lower risks of other adverse outcomes.

Women who have symptoms can be evaluated via physical examination and one of several

laboratory tests. Although the woman may be asymptomatic, common physical examination findings include an inflamed and irritated vulva with minor excoriations, and possibly a frothy, thin, yellow-green vaginal discharge. The vagina and cervix may be a deep red or pink, known as “strawberry cervix.”

The CDC recommends the use of tests specific for detection of *Trichomonas vaginalis*. NAAT tests are very sensitive. Other tests, such as the APTIMA assay, the OSOM *Trichomonas* Rapid Test, and Affirm VP III, are also approved for diagnosis using samples from a variety of sources, including the vagina, endocervix, and urine. These tests can be performed in clinic laboratories for on-site diagnosis. While these tests are expensive, they provide greater diagnostic certainty.

A saline wet-mount microscopic evaluation has historically been used to diagnose trichomoniasis and is still commonly employed. The criteria for diagnosis with this method are (1) vaginal pH higher than 4.5, (2) positive whiff test, and (3) motile trichomonads visualized under the microscope. It is important to remember, however, that the absence of these criteria does not rule out infection because the detection rate is only 65% with this method.[7] Trichomonads are very sensitive to salinity and temperature. If the saline has been left open and become more concentrated, the trichomonads will be lysed. If the sample becomes cold, the trichomonads will not be mobile and will be difficult to distinguish from other cells. The CDC advises clinicians to move toward more sensitive and specific tests when possible.

While the presence of *Trichomonas vaginalis* may be reported on Pap tests, this finding should not be used for diagnosis due to high rates of false-positive and false-negative findings.[7]

Treatment of Trichomoniasis

Treatment options for trichomoniasis are listed in **Table 14-20**. Oral therapies are required, as topical treatment with metronidazole is not effective in eradicating infection. Counseling includes avoidance of alcohol for 24 hours after treatment with metronidazole (Flagyl) and for 72 hours after treatment with tinidazole (Tindamax).[7] Current sexual partner(s) should be treated, even if they are asymptomatic. Both partners should abstain from sexual contact until after treatment is completed and symptoms have resolved. If the initial treatment fails to eliminate the symptoms and trichomonads, consider tinidazole or the longer course of metronidazole. For strains resistant to both these drugs, contact the CDC for susceptibility tests and additional treatments.[7] Rescreen women 3 months after treatment, if possible, to test for reinfection.

Table 14-20 **Treatments for Trichomoniasis in Adults**

Recommended Treatments for Nonpregnant Women and Males Generic (Brand)	Alternative Treatments for Nonpregnant Women and Males Generic (Brand)	Recommended Treatments for Pregnant Women Generic (Brand)	Recommended Treatments for Breastfeeding Women Generic (Brand)
Metronidazole (Flagyl) 2 g orally once	Metronidazole (Flagyl) 500 mg orally twice a day for 7 days	Metronidazole (Flagyl) 2 g orally once Treat only symptomatic women or women with HIV infection. Treatment does not seem to improve perinatal outcomes and may be associated with preterm birth.	Oral metronidazole (Flagyl) taken in high doses during breastfeeding is not recommended due to active metabolites transferred to the infant via breast milk. The woman may want to consider not breastfeeding for 12–24 hours after taking the large dose of metronidazole. Women can choose the alternative of 500 mg twice a day for 7-day treatment and time breastfeeding to coincide with low plasma levels of the drug.
Tinidazole (Tindamax) 2 g orally in a single dose (Tinidazole is more expensive but has higher cure rates.)			Women should not breastfeed for 72 hours after taking tinidazole (Tindamax). Metronidazole is preferred secondary to the higher maternal plasma levels that occur with the tinidazole 2 g single dose.

Abbreviation: HIV, human immunodeficiency virus.

Management of Trichomoniasis During the Perinatal Period

Only women with symptoms of trichomoniasis or women who are HIV positive need to be screened for this infection during pregnancy. Infection with *Trichomonas* has been associated with an increased risk for prelabor rupture of membranes, preterm birth, and low birth weight as well as greater vertical transmission of HIV. However, treatment with metronidazole (Flagyl) does not appear to decrease preterm birth rates and may increase the risk of this outcome.[99] Until she is treated, the woman can still transmit the infection. Partner treatment can occur at any time but may need to be repeated when the woman is treated to prevent reinfection.[7]

Transfer of trichomoniasis to a fetus or newborn during vaginal birth is rare but can happen. The newborn may present with fever and either respiratory or genital infection.

Pubic Lice (Pthiriasis)

Pubic lice (*Pthirus pubis*; **Figure 14-7**), also known as "crabs," are found on coarse body hairs, including pubic, axillary, and occasionally facial hair (eyebrows, eyelashes, or beard). Women usually present with itching and report of visible lice or nits. Sexual transmission is most common, as parasites are pushed onto a new host's hair. However, pubic lice can live for as long as 44 hours off the body, so transmission via fomites such as towels, linens, and other objects is possible. Scalp infestations are not common but can occur, especially in advanced cases.

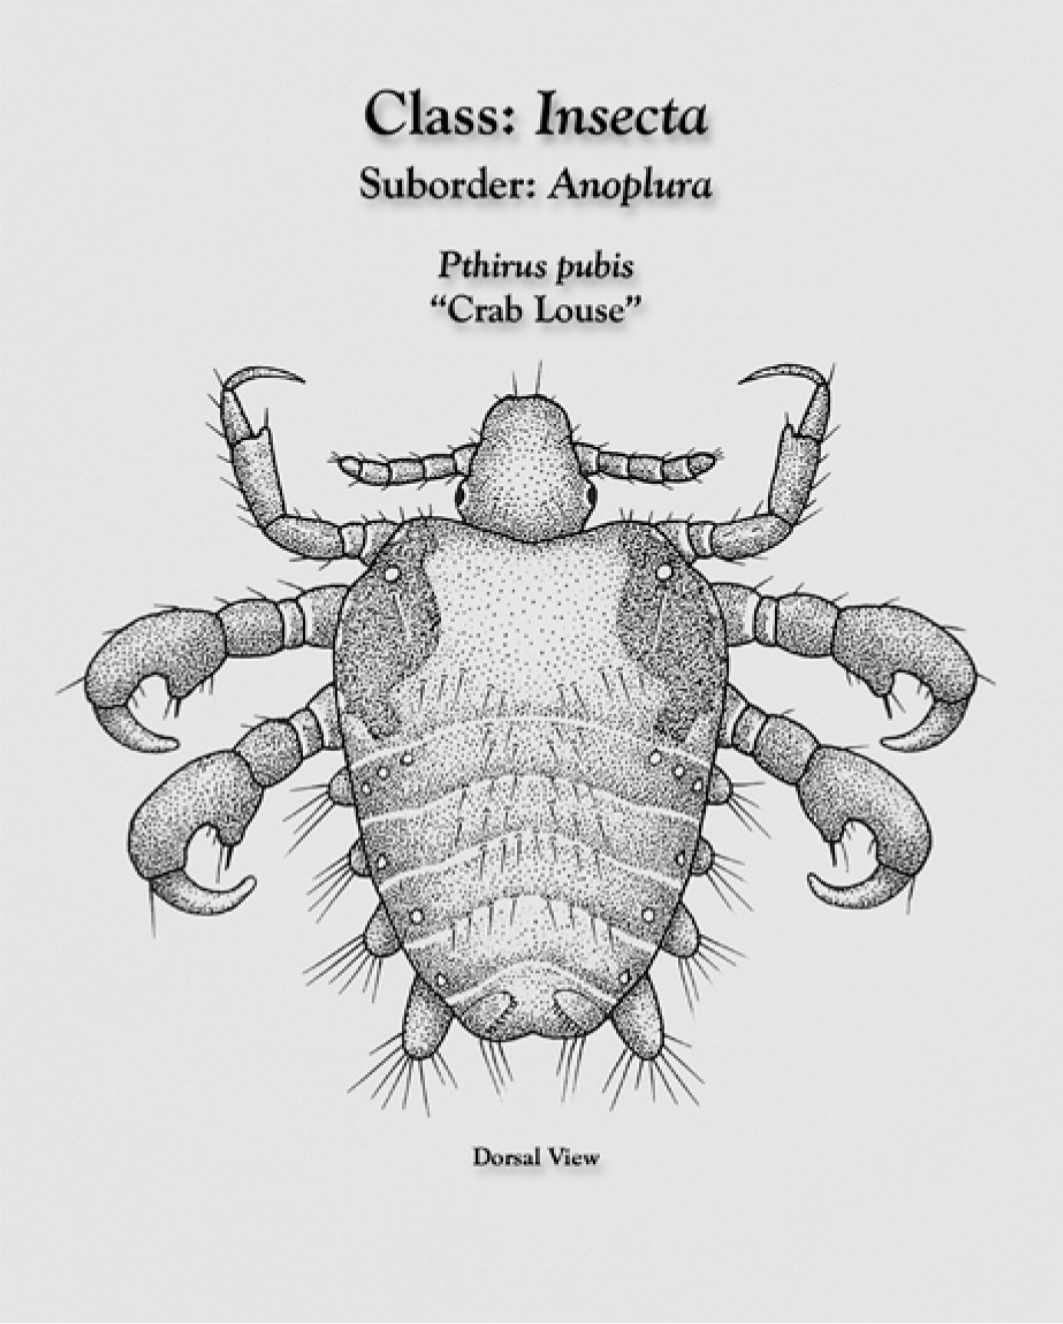

Figure 14-7 Pubic lice.

Courtesy of CDC.

While rare, head lice can occasionally be found in the genital area, especially if pubic hair is fine. Head lice (*Pediculus humanus capitis*; **Figure 14-8**) and pubic lice can be differentiated by their appearance, as pubic lice have a characteristic crab-like appearance and have a lower length-to-width ratio than head lice.

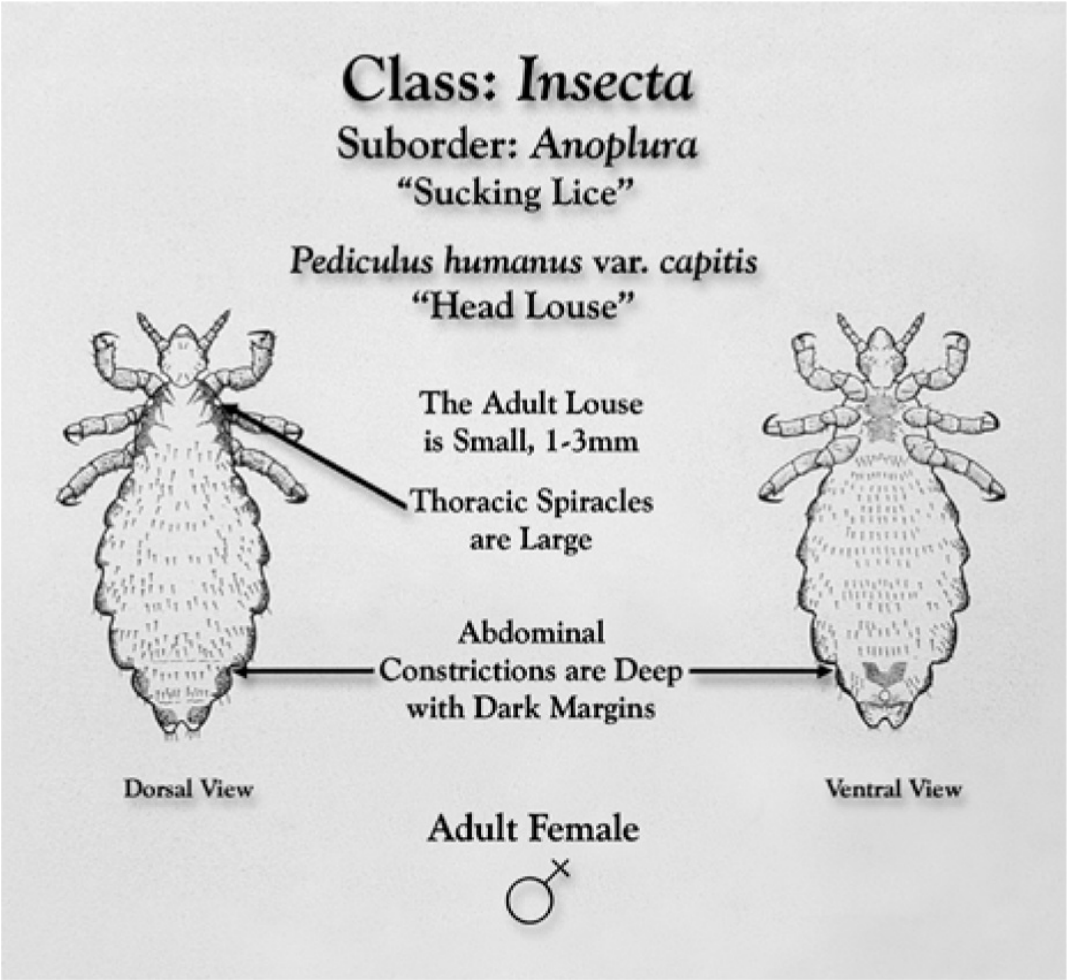

Figure 14-8 Head lice.

Courtesy of CDC.

Diagnosis of Pubic Lice

All hairy or shaved areas of the body are inspected to differentiate the type of infection. Lice and nits are visible on hairs in one or more body area(s), with coarse hairs being more frequently infested than scalp hairs. Small punctuate lesions and bluish macules may also be seen. Lice can be viewed under the microscopic for confirmation, but the physical examination is all that is needed for diagnosis.

Treatment of Pubic Lice

Table 14-21 lists the CDC-recommended treatments for all body areas except the eyes. Pubic lice infestation of the eyelashes should be treated with occlusive ophthalmic ointment twice a

day for 10 days.[7] All clothing and bedding should be washed and dried on a hot setting, dry cleaned, or kept from body contact for 72 hours. Bagging items is more affordable for women who do not have a washer or dryer.
